Selection for divergent geotactic and phototactic maze behaviour in *Drosophila* is also thought to decrease reproductive fitness. The evidence is indirect and based on the observation that suspension of selection pressures in strains of *D. pseudoobscura* resulted in the reversion of the positive and negative geotactic and phototactic strains towards their original neutral maze response[7]. No decrease in productivity has, however, been found in divergent geotactic strains of *D. melanogaster* during 10 generations of selection[8]. This present study was undertaken to investigate directly the reproductive fitness of strains of *D. melanogaster* selected for positive and negative geotactic and phototactic maze behaviour.

Fifteen-unit classification mazes[9,10] were used to select experimentally for divergent geotactic and phototactic behaviour. Maze scores may vary from 1 to 16 on both geotactic and phototactic mazes. A score of 1 represents the most negative maze response possible and the maximum positive maze response results in a score of 16. A cage population of *D. melanogaster* which was established by hybridising large samples of 20 different wild-type strains, was used to begin selection for opposite geotactic and phototactic behaviour. Divergent behavioural selection was carried out by collecting approximately 300 females and 300 males which were run separately through either the geo-mazes or photo-mazes each generation. Sixty pairs of the most positive and negative individuals were selected as parents to initiate subsequent generations for both types of behaviour. Non-virgin females were run through the mazes so females selected as parents were deseminated by being placed at $-10\,°C$ for 10 min[11]. The geo-strains and photo-strains thus produced were highly divergent having undergone opposite selection pressures for over 40 generations. The degree of divergence is reflected in the mean geotactic and phototactic scores of the four strains. Following 42 generations of geotactic selection the mean score of the geonegative strain was 1.85 and the mean score of the geopositive strain was 14.90. The photonegative strain had a mean phototactic score of 2.01 while the mean score of the photopositive strain was 12.7. The unselected control strain was approximately neutral for both geotactic and phototactic behaviour throughout the selection process.

The following procedure was followed to estimate the egg-to-adult survival, egg hatchability, larva-to-adult survival and female fecundity of the strains under study. Virgin females and males were collected over a 48-h

Table 1 Egg-to-adult survival, egg hatchability and larva-to-adult survival of flies from the geotactic strains and phototactic strains

period and stored in separate half-pint food bottles. At the end of this period 25 pairs of adult flies (an average of 1 d old) were immobilised with ether and placed in an empty half-pint milk bottle. A food surface was placed on the open end of the milk bottle. Each food surface consisted of a Stender dish top filled with 5 ml of the standard medium covered with a circular piece of paper towelling coated with a thin suspension of bakers' yeast. The bottle was inverted after the flies' recovery from the ether treatment. At 12-h intervals thereafter, the bottle was turned right side up and the flies were gently knocked to the bottom of the bottle. The food surface was changed and the bottle was returned to the inverted position. The eggs that were laid during the preceding 12 h were then counted. The first 100 eggs counted on each surface for each 12-h period were transferred into a 37-ml shell food vial in groups of 10. This procedure was continued for 20 d as the females aged from 2 d to 21 d old. Approximately 13 d after each egg transfer the number of adults to eclose from each vial was recorded, giving a measure of egg-to-adult survival.

The number of eggs to hatch was estimated during the egg-to-adult survival experiment when 2 replications were tested for each strain. In this case, at 3-d intervals, the food surfaces were changed prematurely after 3 h. One hundred eggs from each strain were transferred on to a fresh food surface and the number of eggs to hatch was recorded 30 h later. A total of 700 eggs was transferred for each strain. The set of eggs produced during the following 9-h interval were used in the egg-to-adult survival experiment.

Larva-to-adult survival was estimated by transferring 50 first instar larvae recently hatched (from the above food surfaces) into food vials. The number of adults to eclose from these vials was recorded 13 d after the larvae transfer. A total of 350 larvae was transferred for each strain tested.

Initially, a single replication of the positive and negative geotactic strains (generation 42) was investigated for egg-to-adult survival and female fecundity. Subsequently, the egg-to-adult survival, number of eggs to hatch and larva-to-adult survival were measured for the phototactic, geotactic and control strains with 2 replications from each strain being tested for egg-to-adult survival. The egg-to-adult survival values (Table 1) were analysed by calculating a corrected sum of squares value for the replication

means within each strain. These values were summed over all strains and divided by 8, the total number of degrees of freedom, to approximate the variance of a replication mean. A t test (d.f.$=8$) was then used to compare the different paired replication means.

Table 1 reveals that egg-to-adult survival was significantly reduced in members of the geopositive strain compared with flies from the control strain ($t=5.70$, $P<0.01$) and the geonegative strain ($t=3.59$, $P<0.01$). The geonegative flies were not, however, different from the control flies ($t=2.11$, $P>0.05$). Individuals from both phototactic strains were significantly lower in survival value than the control strain flies (photopositive, $t=3.44$, $P<0.01$; photonegative, $t=2.40$, $P<0.05$) but they were not significantly different from each other for this fitness parameter ($t=1.05$, $0.5<P<0.3$).

The percentage of hatchings associated with the geopositive strain was also decreased by comparison with all other strains tested (Table 1). Little difference in larva-to-adult survival was found in the four experimental strains and the control strain. This suggests the decrease in egg-to-adult survival found in geopositive flies is likely due to decreased hatching success of their eggs. The egg-to-adult survival values are, however, on the average, only 0.8 as large as the products of the percentage of hatchings and larva-to-adult survival values. This probably stems from differences in the techniques involved in estimating these fitness parameters. For example, the larval density was greater in the egg-to-adult survival study which may have reduced larval viability and accentuated the between-strain differences, whereas in the larval transfer study the lower larval density resulted in more favourable conditions and larval viability may have been only minimally affected. In fact, by dividing the egg-to-adult survival values by the mean percentage of eggs hatching one can compute the average larval viability under crowded conditions (last column Table 1). This shows that the larval viability is reduced in all strains under the crowded conditions with the geopositive flies showing the lowest larval variability.

No differences were found in female fecundity among flies from the geotactic strains (generation 42) and the control strain. The mean number of eggs laid per female per d was 38.4 for the geopositive females, 34.6 for the geonegative females and 35.3 for the control females.

In summary, selection for divergent geotactic maze behaviour has reduced the egg-to-adult survival rate of the geopositive flies with no similar change observed in flies from the geonegative strain. This decrease in viability seemed to be the result of lowered egg hatching success and a decrease in larval viability in crowded cultures. A slight decrease was observed in egg-to-adult survival of both phototactic strains, but the photopositive flies were not different from the photonegative flies.

A decrease in reproductive fitness, as found in the phototactic flies, is not unexpected after experimental selection. The reduced egg-to-adult survival found in geopositive flies but not in geonegative flies is, however, surprising. What are the possible explanations for this differential decrease in reproductive fitness?

Latter and Robertson[12] also found an asymmetrical decrease in fitness in strains of *D. melanogaster* subjected to independent selection for 3 traits (abdominal bristle number, wing length and sternopleural bristle number). They observed that flies from the low selected strains were more reduced in reproductive fitness than flies from the high selected strains. It was concluded that some loci acted pleiotropically, influencing reproductive fitness and the selected phenotype. A reduction in fertility was noted by Wigan and Mather[2] and Mather and Harrison[1] while selecting for chaeta number in strains of *D. melanogaster*. Decreases in fitness were found to accompany the initial generations of selection, but after selection pressures were

relaxed, the fitness of individuals from the selected strains was observed to increase. These results led to the hypothesis that genes influencing fitness were linked with those being directly selected. Selection favouring unique gene arrangements that control the morphological trait being selected was felt to disrupt concomitantly the fitness controlling genes. The increase in fitness after suspended selection pressures may represent crossover events which "release" the polygenes under direct selection from the fitness controlling genes.

In my own experiment an additional possible explanation is that the different selective pressures associated with geopositive and geonegative selection may be responsible for the asymmetrical decrease in fitness. The lack of egg-to-adult survival rate differences between the photonegative and photopositive flies supports this idea. The phototactic maze is horizontal and members of divergent phototactic strains would traverse the maze expending equivalent amounts of energy. Because geonegative selection favours flies that can walk through the entire vertical maze opposing the pull of gravity, those flies must also be the hardiest and the most vigorous. Flies selected in the geopositive direction, in contrast, may include individuals that weakly stumble downwards, as well as those that walk purposefully down. Selection of the most energetic individuals in the geonegative direction may counteract the normally deleterious effects of experimental selection. While selection in both directions favours those individuals homozygous for geobehavioural genes, the concomitant selection for vigour in the negative direction may reduce the deleterious effects of inbreeding. King[13] studied inbreeding in rats and demonstrated that selection for vigour does offset its fitness-reducing effects. Selection of weak and stumbling flies in the positive direction may have directly favoured the least fit and most homozygous individuals.

A simple mechanism for population cycles

ALTHOUGH most animal populations exhibit irregular fluctuations, there has long been considerable interest in the dynamics of populations which seem to fluctuate in a cyclic manner with a period different from that of obvious environmental 'drivers'. We have analysed possible models of the mechanisms underlying the regulation of populations in order to simplify the extraction of useful information from specific cases of population oscillation.

Existing models of cycling populations involve one of three mechanisms:

● The population is assumed to be a component of a stable but underdamped system—that is, in the absence of environmental noise the system approaches equilibrium in a series of damped oscillations. Cyclic behaviour is interpreted as the response of such a system to random noise. The amplitude of the oscillations is then a random variable, the mean value of which depends on both the internal damping and the external noise. The period of the oscillations is determined largely by interaction within the system although the noise causes a steady loss of phase information. A mechanism of this type is implied in Moran's[1] representation of the Canadian lynx cycle.
Fig. 1 Quasi-cyclic fluctuations in the time-delayed logistic model. The population is responding to fluctuation in the carrying capacity, K, of the form $K(t) = K_0(1 + \gamma(t))$ where $\gamma(t)$ is Gaussian white noise with standard deviation $\sigma = 0.1$. The intrinsic growth rate r and the time delay τ are chosen so that $r\tau = 1.4$, a value for which the system is underdamped.

● The population is again represented as part of a stable, underdamped system but the control mechanism is assumed to be nonlinear. In a strongly seasonal environment population cycles may then occur as a result of subharmonic resonance. We have previously[2] illustrated this effect in the time-delayed logistic model with strong periodic variation in the carrying capacity and Bigger (private communication) has suggested that the oscillations[3] in populations of the leaf miner *Leucoptera caffeina* (Washb.) may be of this type.

● The population is assumed to be limit cycling (possibly with some environmental fluctuations superimposed on the limit cycle). Both the amplitude and the period of the oscillations are then determined by the interactions within the system. Many examples have been discussed by May[4].

We have deliberately excluded from the above classification models like Bulmer's[5] of the Canadian lynx cycle which explain cycles in one population (lynx) as being driven by cycles in another population (snow-shoe hare) but which beg the question of the origin of these driving cycles.

The last two mechanisms—subharmonic resonance and limit cycling—involve complicated nonlinear effects and yet they have received considerably more attention from modellers than the first. Our aim here is to advocate the first mechanism as a paradigm for population cycles, since we feel that its obvious simplicity makes it a strong candidate for representing a seemingly cycling population in a fluctuating environment. Particularly appealing is the fact that the principle of the mechanism follows from a purely linear analysis.
Fig. 2 Quasi-cyclic fluctuations in a damped Lotka–Volterra predator–prey model with a fluctuating predator death rate. The parameters are chosen to make the system underdamped. The continuous and dotted curves denote respectively the predator and prey.

We represent by $x(t)$ the difference between the instantaneous population value and its mean value, and by $\bar{x}(f)$ the Fourier transform of $x(t)$. The square of the modulus of $\bar{x}(f)$ is called the spectral density and is denoted by $S(f)$. If $p(t)$ denotes the fluctuation in some environmental parameter then provided it is small, the nature of the resulting population fluctuations can be deduced from the relationship

$$\bar{x}(f) = T(f)\bar{p}(f)$$

where $T(f)$ is known as the transfer function. We have previously[2] derived a transfer function for a simple population model and discussed its interpretation in some detail; here we need only note that an underdamped system is characterised by a peak in the transfer function. At high frequencies the transfer function of a stable system is always very small, essentially because a population does not respond to frequencies much greater than the reciprocal of the smallest ecological time constant in the system. Thus if (and only if) Fourier analysis of time series of relevant environmental variables reveals fluctuations which have a flattish spectrum over the range of frequencies for which the magnitude of the transfer function is significant, it is safe for the purpose of population analysis to represent these fluctuations as white noise. Where this idealisation is permissible, the population spectral density is proportional to $|T(f)|^2$.

Whenever environmental fluctuations lead to a peak in the population spectral density, quasi-cyclic behaviour results. Moreover, the argument in the previous paragraph guarantees that any underdamped system will respond in a quasi-cyclic manner to environmental fluctuations with a flattish spectrum. In Fig. 1 we show an example of quasi-cyclic population fluctuations obtained from a time-delayed logistic model with a time delay chosen to correspond to very light damping, and a randomly fluctuating carrying capacity. In Fig. 2 we illustrate the same behaviour in a damped Lotka–Volterra predator–prey model[6] with random fluctuations in the predator death rate. We have obtained similar cycles when analysing the effects of fluctuating mortality in a single-species model with age structure, and in a model of experiments[7] in which persistence in a spatially heterogeneous, predator–prey system is achieved through a balance of migration and local extinction. This work will be reported in detail elsewhere.

We have given a simple linear analysis of a mechanism which can generate oscillations. In principle, this treatment ought to be applicable only to very small oscillations, but we have carried out extensive numerical simulations of the above models and conclude that the linear analysis is remarkably accurate in predicting the size and nature of the population fluctuations right up to the point where extinction of the population on an ecological time scale becomes highly probable. Thus we conclude that population cycles of rather large amplitude may occur when an underdamped control system is subject to random environmental noise, and we suggest that this mechanism is worthy of consideration when analysing real population data.

We thank Mr M. Pettipher for assistance with the numerical analysis.

Monogamy and duetting in an Old World monkey

THE first monogamous mating system among Old World monkeys has been discovered in the Mentawai langur, *Presbytis potenziani*. The only known monogamous anthropoid primates were the Old World gibbons (*Hylobates* spp.)[1] and a few New World monkeys[2-4]. Reproductive groups of all known Old World monkeys, represented by approximately 85 species, are either polygamous or promiscuous[5].

The endemic Mentawai langur is an arboreal folivore confined to Siberut, Sipora, North Pagai and South Pagai islands, 85–145 km west of Sumatra[6]. Our main study population was nine langur groups inhabiting a study area covering 200 ha in central Siberut Island, near the headwaters of the Sirimuri River (1°24′S, 99°1′E). Between July 1972 and November 1974 we spent 447 d and made over 160 h of visual observation of undisturbed Mentawai langurs at this site.

Adult Mentawai langurs exhibit little sexual dimorphism. Ten specimens (6 males, 4 females) show a female–male weight ratio of 0.98 (mean weight: male 6.5 kg; female, 6.4 kg). The only difference in coat coloration between the sexes is the male's conspicuous white genital fur patch.

The 21 groups of langurs we observed were adult pairs with up to four younger animals. Females bear a single infant approximately once every other year. Mean size of nine families studied regularly varied from 3.4 in March, 1973 to 4.0 following the 1974 July–August birth season. Adult pairs remained together for the entire 2.5-y study.

We did encounter six solitary males. These solitary males account for 22% (6/27) of our adult male sample. All adult females observed were monogamously mated. But all-male groups, typical of other polygynous langurs[4], were never encountered.

Families occupy a home range of about 15–22 ha. Home ranges of adjacent groups overlap extensively, but each contains an exclusively used "core area"[7] where their sleeping trees (mean = 2 per group) are located. Core areas are situated on major ridge crests, on boundaries between gibbon (*Hylobates klossii*) territories. Intrusion by alien langur males into core
Fig. 1 Ink tracings of audiospectrograms illustrating a typical, duetted intergroup call by a mated pair of Mentawai langurs. The three prolonged (about 0 5 s) sounds terminating the duet are those of the female. The first sound overlaps the stacatto terminal trill of the male's vocalisation. Note the two components to the male call; a series of harsh, biphasic sounds corresponding to inhalation and exhalation, followed by a slow, tonal trill. The vocalisations were recorded in the field at 9.5 cm s with a Uher 4400 tape recorder and a Sennheiser 405-S microphone fitted to a parabola 60 cm in diameter. Audiospectrograms were made with a Kay Elemetrics sound spectrograph on wide band setting.

areas results in aggressive inter-male confrontations dominated by loud vocalisations and visual display by owner and trespasser.

Like adult females in other monogamous primates, female Mentawai langurs participate with their mates in vocal and visual displays directed towards adjacent groups. Males emit loud vocalisations (audible to about 1 km), either spontaneously or on hearing or seeing members of other groups. They are comparable to the intergroup "spacing" calls of other male colobines[5]. Male intergroup calls are accompanied by a vigorous jumping display on branches. This shakes the entire tree crown. When the males make intergroup calls, their mates respond by adding a characteristic 3–4-syllable coda (audible to about 0.5 km) to the end of it (Fig. 1). She then leaps from branch to branch, shaking the tree after the male has stopped his display. In other colobines such displays are given only by males[6].

The vocal portion of the Mentawai langur intergroup display, with its male and female components, resembles the duetting gibbon pairs[5], titi monkeys[2], and monogamous tropical birds which remain paired throughout the year[10,11]. Thus the correlation of duetting with permanent, year-round monogamy

Table 1 Behavioural response of Mentawai langurs to man

	Mated pairs with immature young	Mated pairs only	Solitary males
Distraction display	12	0	0
Cough alert	5	7	0
Rapid flight with no vocalisations	1	10	18
Total (n = 53)	18	17	18

in birds and primates can be extended to the Mentawai langur, and the hypothesis that duetting functions to maintain monogamous pair bonds[10–13] is supported.

Adult male Mentawai langurs perform distraction displays in response to man, the major and perhaps only predator on primates in Siberut. Other relevant predators such as large raptors or felids do not occur on these islands[6]. Another basis for the relatively great impact of man as a predator on Mentawai primates is the dominance of primates in the island's depauperate mammalian fauna Primates constitute 82% of all large mammalian prey taken by aboriginal hunters in Siberut. Thus, both the more intensive human predation and the lack of counterselection favouring alternative predator defence strategies probably account for the Mentawai langur's distraction performance in encounters with man.

The adult male distraction display is a loud vocalisation accompanied by branch bouncing, delivered every 20–30 m as he runs through the canopy. Vocalisations resemble the harsh, biphasic syllables of the intergroup call (Fig. 1), but the female remains silent. During this performance the female and immature young often hide silently and motionless in the canopy for periods up to 45 min before leaving. On five different occasions a displaying male made a complete circle after calling 6–8 times, entered the tree his family occupied, then again began a new distraction directed towards the observer.

The presence of offspring is significantly correlated ($\chi^2 =$ 51.9; $P < 0.001$) with the male's distraction display. For the 35 cases involving either solitary males or mated males with no offspring, langurs fled without giving alarm calls. Occasionally the male coughs harshly (7 of 17 events) if his mate is feeding in another tree. The cough (audible to about 50 m), may alert the female of danger and the male's intention to begin rapid movement. It may precede the louder call (audible to about 1 km) family males emit in response to man (Table 1).

Thus, several interrelated characters closely linked to monogamy in other species typify the Mentawai langur. Its lack of sexual dimorphism extends the correlation between monogamy and monomorphism[13,14]. The monogamous pair bond is maintained by vocal duetting and mutual visual displays The distraction display of family males is risky but increases the survival chances of his own offspring.

acquired in the allopatric state[1-4]. One of the major problems of evolutionary genetics is, then, characterisation of the genetic differences which actually produce the reproductive and sexual isolation characteristic of species. A partial answer to this problem has been provided by estimating the degree of structural gene divergence over various taxonomic levels—populations, subspecies, semispecies, sibling species and morphologically distinguishable species[5,6]. The general picture emerging from these studies is moderate structural gene differentiation at the subspecies level. Once reproductive isolation has been achieved, little additional change seems to be required to establish sexual isolation between subspecies. There are, however, exceptions to this generalisation[7,9], and they do not seem to be infrequent. Speciation may occur as a result of chromosomal rearrangements, accompanied by little, if any, detectable change in the structural genes usually studied.

Attempting to explain the preponderance of sterility and inviability in the heterogametic progeny of hybrid matings, Haldane[11] suggested that sex chromosome translocations might be the cause. Tracey[12] estimated fixation probabilities

of an X·Y^L and a Y^S chromosome in laboratory populations of *Drosophila melanogaster*. The estimated probability of fixation exceeded neutral expectation for both of these translocation chromosomes; moreover X·Y^L//Y^S males had a mating advantage compared with X·Y^L//Y males when the females competed for were X·Y^L//X·Y^L. We have examined the genetic basis of this mating advantage and found that it is primarily determined by the Y^S chromosome, with the Y^L segment attached to the X and the *yellow* allele playing significant but lesser roles. In addition we have found that a population of *D. melanogaster* bearing X·Y^L, Y^S and the *yellow* allele exhibits significant sexual isolation with respect to a karyotypically normal strain homozygous for the eye mutant *sparkling-poliert*.

The X·Y^L chromosomes of all females used to test mating advantage carry the markers *yellow, forked* and *carnation*. Three Y chromosomes have been used: a normal Y, a Y^S which lacks the Y^L arm but is fertile when X·Y^L//Y^S and a Y^S bearing a translocated normal allele of *yellow* designated Y^S, y^+. Observation chambers[13] were used to study mating; the genotypes used were produced by crossing to

Table 2 Multifactor genetic basis of X·Y^L/ /Y^S male mating advantage

	X chromosomes (A)	(B)	Y chromosomes (A)	(B)	A mating frequency	n	χ^2 probability
(1)	X·Y^L	compared with X	Y^S	compared with Y^S, y^+	0.71	63	0.001*
(2)	X·Y^L	compared with X·Y^L	Y^S, y^+	compared with Y	0.71	147	0.001*
(3)	X·Y^L, y^+	compared with X·Y^L	Y^S	compared with Y	0.67	60	0.014†
(4)	X	compared with X	Y^S, y^+	compared with Y	0.76	80	0.001*
(5)	X	compared with X·Y^L	Y^S	compared with Y^S, y^+	0.31	48	0.014†
(6)	X	compared with X·Y^L	Y	compared with Y^S, y^+	0.09	53	0.001*
(7)	X, y^+f^+car$^+$ compared with X, f^+car$^+$		Y	compared with Y^S	0.93	30	0.001*

Male genotypes were combinations of columns A/ /A and B/ /B; as in Table 1, female genotypes were always X·Y^L/ /X·Y^L, $y f car$, and 24 females were used in each chamber. Twelve males of each genotype were used and they were $y f car$ except where wild alleles are noted. n, Total number of matings observed.
Goodness-of-fit χ^2 probabilities were corrected for continuity where the associated probability was less than 0.10.
*$P<0.005$.
†$P<0.05$.

a locally collected wild-type stock and selecting the desired recombinants.

Yellow males are known to mate less frequently than their normal counterparts[14,15]; therefore, we first compared *yellow* and normal bodied males (Table 1). There is no demonstrable difference in mating success between these males when they are fertile except for flies with normal chromosomes. X//Y males of normal body colour show a significant mating advantage. Similarly, the presence or absence of the Y^L segment on the X chromosome does not significantly affect mating success when this is the major genetic difference between competing males. Note, however, that the equivalence of *yellow* and normal male mating frequency does not hold when the males lack the Y^L segment and the Y^8 carries a y^+ marker. When Y^8- and Y-bearing males are compared, the Y^8 males do significantly better when they are fertile regardless of body colour. The absence of the Y^L segment on the X not only makes X//Y^8 males sterile, but also eliminates the mating advantage for flies of normal colouration. When *yellow* X//Y^8 and X//Y males competed, a nearly significant excess of X//Y^8 matings was observed. If this difference is real, it seems that the *yellow* allele and the Y^L segment interact with the Y^8 to produce the mating advantage observed in X·Y^L//Y^8 males.

Further evidence of interaction is presented in Table 2 which summarises mating chamber studies in which both the X and Y chromosomes of males differed. Comparison of studies 1 and 5 (Table 2), in which all Y chromosomes were Y^8 but the *yellow* marker and the X·Y^L chromosome were juggled, suggests that *yellow* males are more readily accepted by X·Y^L//X·Y^L females when the males carry the X·Y^L. In the presence of a normal X chromosome, the *yellow* mating advantage disappears. The comparisons of X·Y^L and X males (Table 1) indicate that this difference is attributable to a *yellow* by X·Y^L interaction. Males of normal body colour mate more frequently when they are of normal karyotype or carry a Y^8 marked with y^+ (Table 1, A5 and 6; Table 2, studies 2, 4, 5 and 6). The body colour equivalency apparent in Table 1, however, indicates that this advantage is an effect of the Y^8 rather than the y^+ allele. Moreover, X//Y^8 males are sterile; any mating advantage of such males is meaningless in an evolutionary context.

Thus, mating advantage of X·Y^L//Y^8 males is primarily affected by the Y^8 chromosome and augmented by a *yellow* –X·Y^L interaction. As X·Y^L//Y^8 is fitter than X//Y when females are X·Y^L//X·Y^L, it is important to assess the degree to which an X·Y^L–Y^8 system is sexually isolated from normal, X–Y populations of *D. melanogaster*. Conclusive tests of the degree of sexual isolation attributable to the translocation and to the *yellow* marker will require extensive homogenisation of genetic background. We have, however, obtained exciting results in a preliminary test. Males and females from the X·Y^L, *y f car*; Y^8 stock were placed in observation chambers with a wild strain containing the marker gene *sparkling–poliert* eye. The degree of homogametic mating exceeds 82%; 70 of 85 matings were between males and females of the same stock. This difference is highly significant and yields a sexual isolation coefficient equal to 0.65 ± 0.08; a value in excess of those obtained for populations and subspecies of *D. willistoni*[16], but within range of values obtained for semispecies of *D. paulistorum*[17].

To the extent that we may extrapolate from laboratory studies, these and previous[13] results suggest that speciation may occur with minimal genic change. The fixation of X·Y^L and Y^8 in an isolated population is a virtual certainty given sufficient time. In the absence of other change this X·Y^L–Y^8 population is reproductively isolated from its progenitor. The additional substitution of the *yellow* allele, which is itself advantageous in some conditions[14], engenders both a greater mating advantage and a rather high degree

of sexual isolation. In the light of the high frequency of sex chromosome polymorphisms, within and among species[19,20], and the low degree of genetic divergence between some of these species[7,9], Haldane's explanation of reproductive isolation requires serious consideration.

Lipoprotein of Gram-negative bacteria is essential for growth and division

THE lipoprotein of Gram-negative bacteria has become a cell surface component of central interest following its characterisation by Braun and coworkers[1]. This small protein (molecular weight 7,500) is unique in containing as its N-terminal amino acid a glycerylcysteine to which three fatty acids are covalently bound[2]. It is also unusual in its subcellular distribution: one-third of the total lipoprotein is covalently linked to the cell wall peptidoglycan while the remaining two-thirds exists in an unlinked or "free" form in the outer membrane[4]. Free and murein-linked lipoprotein seem to be identical in structure[4,6], and pulse–chase experiments indicate that free lipoprotein is the precursor to murein-linked lipoprotein[4]. Braun's lipoprotein or an immunologically related protein has been found in a wide variety of Gram-negative organisms[7,8], and in *Escherichia coli* is present in about 3×10^5 copies per cell[1]. These observations suggest that lipoprotein performs some essential function(s); however, the nature of that function is unknown. It has been suggested that lipoprotein may have a role in anchoring the outer membrane to the cell wall[5], or function in transporting small molecules through the outer membrane[9] or be involved in cell division[10,11]. To clarify the role of Braun's lipoprotein, we have isolated a mutant deficient in its synthesis.

The procedure used for isolation of the mutant was based on some of the unusual properties of the lipoprotein. The primary amino acid sequence of Braun's lipoprotein has been determined[12]; it has been found to lack five amino acids, including proline, histidine and tryptophan. Hirashima and Inouye[13] have demonstrated that during starvation for these amino acids, *E. coli* continues to synthesise lipoprotein, although synthesis of other proteins is drastically reduced. This observation suggested the possibility of enriching for a lipoprotein mutant by starving cells for proline, histidine and tryptophan, labelling with arginine, and performing a suicide selection. Since 42% of the total radioactivity incorporated by our strain

after amino acid starvation was found in lipoprotein (as compared to 3% in normal conditions), on prolonged storage a mutant which had not synthesised lipoprotein should survive longer than wild type. Two additional considerations taken into account were that lipoprotein might be essential for growth, and that the suicide would only enrich for mutants which either did not synthesise the protein or degraded it very rapidly. This prompted the use of a strain carrying a temperature-sensitive amber suppressor, which would allow the isolation of a conditional amber mutant in lipoprotein.

To perform the suicide selection, a strain which carried a temperature-sensitive suppressor and which could be starved for the appropriate amino acids was constructed by transducing D117 (an *E. coli* K12 strain of genotype *pro⁻his⁻trp⁻Su⁻Δlac/-F'lac⁻* amber) with bacteriophage P1 grown on *E. coli* MB188 (*trp⁻*am *SuIII*-A81 ts from K. Begg). A transductant was selected which was phenotypically *lac⁺trp⁺* at 30 °C and *lac⁻trp⁻* at 42 °C; the transductant also showed temperature sensitivity in its ability to allow growth of amber phage. It was cured of the episome by acridine orange. The resulting strain

Fig. 2 Effect of temperature shift on growth and viability of ST715. ST715 was grown at 30 °C in L broth[26] and at time 0 diluted 1/10 into prewarmed (42 °C) L broth. Viable counts (O) and absorbance (●) were measured. The solid line is a growth curve (absorbance) of the parent (M7) at 42 °C.
Fig. 1 SDS–acrylamide gel electrophoresis of envelope fractions from M7 and ST715 grown at 30 and 42 °C. M7 and ST715 were grown at 30 °C in minimal medium, filtered, and resuspended in medium containing cold arginine (2 µg ml⁻¹). A portion of each culture was shifted to 42 °C, and aliquots withdrawn after 30, 60, and 90 min. Each aliquot was labelled at 42 °C for 30 min by the addition of ¹⁴C-arginine (1 µCi ml⁻¹, specific activity 277 mCi mmol⁻¹). Control cultures (M7 and ST715 at 30 °C, M7 at 42 °C) were labelled 30 min after shift. Cultures were collected and envelope fractions prepared. These were dialysed overnight against 0.01 M Tris-HCl pH 6.8 at 4 °C, and collected by centrifugation at 90,000*g* for 60 min. Envelope fractions were solubilised in sample buffer[23] containing 0.5% SDS and applied to a 12.5% acrylamide slab gel[24] containing 0.5% SDS along with molecular weight markers. The gel was stained with Coomassi brilliant blue[25], dried and autoradiographed. Sample wells contain: *a*, M7 labelled at 30 °C, 60,000 c.p.m. applied; *b*, M7 labelled at 42 °C, 115,000 c.p.m. applied; *c*, ST715 at 30 °C, 40,000 c.p.m. applied; *d*, ST715 after 30 min. at 42 °C, 50,000 c.p.m. applied; *e*, ST715 after 60 min at 42 °C, 30,000 c.p.m. applied; *f*, ST715 after 90 min at 42 °C, 27,000 c.p.m. applied; *g*, same as *b*. Molecular weight standards were bovine serum albumin (68,000), DNase (31,000), trypsin (23,800), cytochrome *c* (12,400) and insulin (5,700). Free lipoprotein migrates immediately behind the front and is indicated by an arrow. The band of slightly higher molecular weight migrating behind free lipoprotein is presumably murein-linked lipoprotein which has been released by endogenous murein hydrolases. This assumption is based on the fact that neither band contains histidine (data not shown), and that the synthesis of both seems to decrease in a coordinate fashion during incubation of ST715 at 42 °C.
M7 (*pro⁻his⁻trp⁻*am *SuIII*-A81 ts), was mutagenised to 5% survival with nitrosoguanidine[14] diluted 1/10, and allowed to grow overnight at 30 °C in E medium[15] supplemented with the required amino acids. The culture was filtered, washed, resuspended in 50 ml E medium lacking proline, histidine, and tryptophan, and incubated at 42 °C for 60 min. ³H-arginine (50 µCi ml⁻¹, specific activity 28.7 Ci nmol⁻¹) was added, and incubation at 42 °C continued for 90 min. The cells were collected by filtration, washed with minimal salts containing unlabelled arginine (500 µg ml⁻¹), and then washed with cold water to remove pools of unincorporated radioactive arginine. The cells were resuspended in cold E salts and stored at 4 °C. Viability was measured at intervals by plating at 30 °C. The cell titre decreased exponentially, and had fallen from an initial value of 1 × 10⁸ ml⁻¹ to 3 × 10² ml⁻¹ after 45 d. Unlabelled control cells decreased in viability by less than 50% during this time. After 45 d, all surviving cells were plated on minimal plates and screened for temperature-sensitive growth on nutrient agar plates. Of 23,000 total survivors obtained from several experiments, 513 were temperature sensitive, and these were assayed for lipoprotein synthesis at 30 and 42 °C.

One of the temperature-sensitive survivors was found to synthesise reduced amounts of murein-linked lipoprotein at 42 °C (Table 1). Murein-linked lipoprotein accounts for 3.2% of the arginine incorporated into the envelope fraction of M7 at 30 °C; this figure is slightly higher at 42 °C. In contrast, strain ST715, although showing normal lipoprotein levels at

Fig. 3 Effect of temperature shift on morphology of ST715. ST715 was grown in L broth at 30 °C (*a*), and shifted to 42 °C for 3 h (*b*). Cells were collected by centrifugation, resuspended on 0.01 M Tris pH 6.8, and stained with 2% uranyl acetate. Micrographs were taken in a Joelco 100B electron miscroscope at a magnification of × 5,000.

Table 1 Assay of murein-linked lipoprotein in parent and mutants grown at 30 and 42 °C

		Total envelope (^{14}C-Arg c.p.m.)	Lipoprotein (c.p.m.)	Lipoprotein/total envelope ratio (%)
M7	30 °C	73,968	2,392	3.2
	42 °C	77,536	3,304	4.3
ST715	30 °C	39,276	1,255	3.2
	42 °C	80,055	636	0.8

This assay is based on the observation[20] that murein-linked lipoprotein can migrate on chromatograms in an isobutyric acid–ammonia solvent after it is released from murein by lysozyme digestion. ST715 and M7 were grown at 30 °C in E medium supplemented with required amino acids and arginine. In the early phase of exponential growth, the culture was filtered and cells resuspended at 30 °C in medium containing arginine (4 μg ml^{-1}). After 10 min, a portion of each culture was shifted to 42 °C and incubated for 30 min; control cultures remained at 30 °C. ^{14}C-arginine (specific activity 277 mCi mmol^{-1}) was added to 0.5 μCi ml^{-1}, and incubation continued for 30 min. Cultures were chilled, collected by centrifugation at 4 °C, washed once with cold saline and re-suspended in 1 ml cold 0.01 M Tris HCl *p*H 6.8. The cells were ruptured by sonication, centrifuged for 5 min at 3,000*g* to remove unbroken cells, and then centrifuged at 90,000*g* for 60 min to collect envelopes. These were resuspended in a small volume of water and boiled for 5 min. A small aliquot was spotted on Whatman 3MM chromatography paper for direct counting; the remaining sample was applied in two equal portions to Whatman 3MM paper and chromatographed overnight in isobutyric acid–1 N NH$_4$OH (5:3) (descending chromatography). This procedure separates murein-linked lipoprotein (origin) from free lipoprotein and other envelope proteins which migrate with an R_f of 0.8. Chromatograms were dried, and a 2-cm region around the origin cut out. One of each duplicate sample was incubated overnight at 37 °C in 2 ml 0.5 N ammonium acetate containing egg white lysozyme 500 μg ml^{-1}; the control was incubated in buffer alone. Incubation with lysozyme releases the lipoprotein from the cell wall material at the origin but does not liberate the lipoprotein from the paper.

The origins were washed twice with water, dried, sewn on to Whatman 3MM paper, and rechromatographed in isobutyric acid–1N NH$_4$OH (5:3) for 4 h. Murein-linked lipoprotein migrates with an R_f of 0.8 during this chromatography. Chromatograms were dried, cut into 2-cm pieces and counted. Each value was corrected for counts released during the control incubation (from 10–20% of the value obtained using lysozyme), and samples were normalised by comparing each lipoprotein value to total envelope counts applied. This assay is specific for murein-linked lipoprotein since there is little release of radioactivity in the absence of lysozyme; the released material contains palmitic acid and diaminopimelic acid but not histidine; when eluted from the chromatogram and subjected to SDS–acrylamide gel electrophoresis, all the material comigrates with *in vivo*-labelled murein-linked lipoprotein (data not shown).

30 °C, shows a fourfold decrease in incorporation into lipoprotein after 60 min at 42 °C. A second survivor also showed a twofold decrease in murein-linked lipoprotein at 42 °C as well as slightly reduced levels at 30 °C (data not shown); this strain was very unstable and further studies were performed on ST715 only.

To determine whether ST715 also showed a temperature-dependent reduction in synthesis of free lipoprotein, M7 and

ST715 were incubated at 30 and 42 °C for various periods of time and then labelled with ^{14}C-arginine. Whole envelope fractions were prepared and subjected to sodium dodecyl sulphate (SDS)–acrylamide gel electrophoresis as shown in Fig. 1. This gel does demonstrate a decrease in synthesis of lipoprotein in ST715 as a function of time of incubation at 42 °C; this decrease is quite gradual, and some synthesis is still detectable after 2 h at 42 °C, presumably reflecting leakiness of the temperature-sensitive suppressor. Other changes in the envelope fraction of ST715 at 42 °C can be seen; notably the appearance and gradual disappearance of a protein band of high molecular weight ($\sim$ 90,000) and the disappearance of a band of $\sim$ 70,000. The relationship of these changes to the lipoprotein lesion is unclear and will be studied in revertants.

The effects of lipoprotein deficiency on cell physiology were studied by shifting an exponentially growing broth culture of ST715 from 30 to 42 °C (Fig. 2). This shift results in an abrupt cessation in the increase of viable counts. Cell mass continues to increase, however, and filaments are formed (Fig. 3). After several hours at 42 °C, viability begins to decrease slowly; at this time cells are 4–8 times their normal length. Thus, continued lipoprotein synthesis seems necessary for cell division.

To determine whether lipoprotein deficiency, filament formation and temperature-sensitive growth were the result of a single mutation, revertants which could grow at the non-permissive temperature were selected. These were found to occur at a frequency of approximately 10^{-9}. Ten revertants were selected for further study, and all were found to have increased levels of murein-linked lipoprotein at 42 °C. Two revertants, E4 and E10, which showed normal growth rates at 42 °C, were analysed for murein-linked lipoprotein and found to have levels comparable to M7 (Table 2). Interestingly, E10 seems to be a wild-type revertant, whereas E4 has apparently reverted to temperature-independent suppression. The fact that activation of a suppressor at 42 °C enables E4 to grow and make lipoprotein at this temperature suggests that ST715 carries an amber mutation. Other revertants studied seemed to be partial revertants, which grew with a greater than normal generation time at 42 °C, and, showed only partial restoration of bound lipoprotein levels at 42 °C (ranging from a two- to fourfold increase over mutant levels in an experiment in which the parental level was 7 times that of ST715). This may indicate that lower amounts of lipoprotein than observed in the parent are sufficient to support growth. The results shown in Table 2 also demonstrate that growth at 42 °C, filament formation, and lipoprotein content are properties linked by transduction. These results indicate that all properties of the mutant are due to a single mutation, and suggest that lipoprotein may be necessary for normal growth and division.

Wu and Lin[21], using a suicide technique similar to that described here, have recently isolated a mutant deficient in linking lipoprotein to murein. Their mutant, like ST715, shows temperature sensitivity in growth and division. Since the strain

Table 2 Properties of revertants and transductants of ST715

Strain	Growth at 42 °C		Plates T4amB25		Morphology		Murein-linked lipoprotein (at 42 °C)/ total envelope ratio
	+ tryp.	− tryp.	30 °C	42 °C	30 °C	42 °C	
M7	+	−	+	−	rod	rod	4.5%
ST715	−	−	+	nd	rod	fil	0.5%
E4	+	+	+	+	rod	rod	4.0%
E10	+	−	+	−	rod	rod	3.1%
TD4	+	−	+	−	rod	rod	5.3%
TD6	+	−	+	−	rod	rod	3.6%

Revertants of ST715 were isolated by spreading approximately 3×10^9 cells on minimal plates and incubating at 39 °C. Revertant clones were purified, tested for amino acid requirements and streptomycin resistance, and grown in minimal medium at 42 °C to determine growth rate. Murein-linked lipoprotein was measured on cultures which had been pregrown at 30 °C, shifted to 42 °C for 60 min, and then labelled at 42 °C for 30 min with ^{14}C-arginine. Growth requirement for tryptophan was determined on plates; phage sensitivity was measured by plating efficiency at 30 and 42 °C; and morphology examined by phase microscopy.
P1 transduction was performed as described[27] using *E. coli* K12 strain GR2131 (genotype *pro-leu-trp-gal-man-xyl-mal-lac-phoA purE* from G. Willsky) as a donor. Transductants which were able to grow at 42 °C were isolated, purified, and tested for amino acid requirements. Two transductants, TD4 and TD6, were assayed for murein-linked lipoprotein and tested for other properties as described above.

isolated by Wu and Lin seems, however, markedly deficient in linking lipoprotein to murein at the permissive temperature, it is possible that murein-linked lipoprotein does not have an essential role in growth and division of *E. coli*. This would imply that it is the deficiency in free lipoprotein which is responsible for the phenotype of ST715. In addition, until it can be shown that ST715 carries a lesion in the structural gene for lipoprotein, it remains possible that ST715 is affected in growth and lipoprotein through a mutation which affects both properties indirectly. An example would be a protease responsible for processing lipoprotein and other essential proteins.

Mutants with reduced levels of other major outer membrane proteins (of molecular weight 30,000–40,000) have been described[14,15] as well as mutants which lack one[16,17] or all[18] of these proteins; however, such mutants are viable and morphologically normal. This is in contrast to ST715, which is unable to grow and divide at the non-permissive temperature when lipoprotein formation is greatly reduced. Braun's lipoprotein thus may serve a more vital function(s) than do these other major outer membrane proteins. Further studies with the lipoprotein mutant described here should define the role of this major component of the outer membrane in cell growth and division.

Prevention of the contagious spread of feline leukaemia virus and the development of leukaemia in pet cats

Clustering of cases of feline lymphosarcoma (LSA) or leukaemia has been observed by veterinarians for many years[1-4]. The first anti-feline leukaemia virus (FeLV) serum was reported in 1969[5] and by 1970 a simple indirect immunofluorescent antibody (IFA) test for the detection of FeLV in the peripheral blood of infected cats had been developed[6]. Using this test we found that 33% of the healthy pet cats exposed to cats with FeLV-associated diseases were infected with FeLV. All the cats known not to have been exposed to cats with FeLV-associated diseases were uninfected and only 0.31% of the stray cats, with an unknown history of FeLV exposure, were infected[3]. Once persistently viraemic with FeLV, most

cats remain infected for their entire lives. These results showed conclusively that FeLV is transmitted between cats by infection or contagion (that is, horizontally), in contrast to the oncornaviruses of inbred mice which are predominantly transmitted genetically from the parents to the offspring by means of the chromosomes (that is, vertically)[7].

FeLV causes four fatal diseases in pet cats. The diseases are: (1) LSA[4,5], (2) non-regenerative anaemia[8,9], (3) a panleukopaenia-like syndrome[3], and (4) thymic atrophy[10]. FeLV is also associated with, but not yet proven to be the cause of, various myeloproliferative disorders[11] and foetal abortions and resorptions (F. Goldsmith and W. D. H., Jr, unpublished)[12,13]. Healthy FeLV-infected cats have a greatly increased chance of developing one of the FeLV-related diseases or of developing secondary diseases due to the immunosuppressive effects of FeLV[12,14].

The spread of an infectious disease agent may be prevented by various methods. These are: (1) vaccination, (2) killing the infectious agent in the environment by disinfection, and (3) removal of either the infected sick animal, the healthy carrier host or the vector(s). In veterinary medicine, when vaccination is not available, removal of the carrier host is commonly used to prevent the spread of infectious disease agents[15].

Our earlier epidemiological studies showed that FeLV is an infectious agent for pet cats[3]. The ultimate goal of any epidemiological study is to prevent the spread of a disease by identifying the aetiological agent so that it can be removed from the environment. We report here the successful use of an FeLV test and removal programme to prevent the spread of FeLV, and the diseases it causes, among pet cats. The FeLV test and removal programme consists of the identification and removal, by euthanasia or isolation, of FeLV-infected healthy cats from contact with uninfected cats[16]. The IFA test for FeLV detects FeLV gs antigens in the peripheral blood leukocytes and platelets of infected cats[3,6] and we have previously reported that a positive IFA test result means that the cat is viraemic[6,13].

In most multiple cat households in this study an index FeLV test was performed on a sick or healthy cat to establish the FeLV status of the households. The index test-positive cat was removed and all the remaining healthy cats in the household were then tested for FeLV (initial test). In the programme, any exposed healthy cats which were found to be infected with FeLV were removed immediately. After the initial test of all the healthy cats, the household was quarantined so that no cats were allowed to leave and no new cats were brought into the household. After a 3-month interval a second test for FeLV was performed on all the remaining healthy cats in the household and any secondarily infected cats were removed. Cats which were FeLV uninfected in the initial test but which were found to be FeLV infected in the second test will be referred to as secondarily infected cats in this paper. Two IFA tests for FeLV are required for exposed cats because the natural incubation period for the establishment of viraemia can be as long as 3 months, and there is a possibility that an FeLV infection, occurring just before the first test, would not be detected in that test[13]. If any healthy cats were positive in the second IFA test they were removed from the household and a third test was conducted 3 months later. When all the cats remaining in a household after the infected cats had been removed were negative in two consecutive IFA tests, conducted 3 months apart, the household was considered FeLV free. All new cats which were introduced into an FeLV-free household were tested for FeLV before they were allowed to have contact with the uninfected cats.

A total of 1,260 healthy cats, from 65 households in which cats had developed FeLV-related diseases and from 11 breeding catteries, have been studied (Table 1). In 51 of these households the test and removal programme was implemented, while in 25 households the owners chose not to implement the programme. These 25 households served as controls and were therefore compared with the 51 households in which the

Table 1 Disease and FeLV status of household groups before the FeLV test and removal programme

Household groups	Number of households	Number of cats with FeLV diseases				Index FeLV test*		Total cats remaining after diseased cats died
		Total cats	Lymphosarcoma	FeLV anaemia	Other	Household status FeLV infected	Not tested	
Households where FeLV-infected healthy cats were removed	51	923	42	6	28	37	14†	847
Households where FeLV-infected healthy cats were not removed	25	472	37	4	18	23	2‡	413
								Total 1,260

*An index FeLV test was the first IFA test of a cat in a household.
†Index FeLV tests were not performed in 10 breeding catteries because no cats had previously developed an FeLV disease. No index tests were performed in the other 4 households where cats had developed FeLV diseases because these cats had died before our study began.
‡An index FeLV test was not performed in 1 household (a breeding cattery) because no cat had previously developed an FeLV disease. An index test was not performed in the other household where a cat had developed an FeLV disease because this cat had died before our study began.

Table 2 Summary of the test and removal programme to prevent the contagious spread of FeLV in healthy pet cats

Household groups	Number of households	Number of healthy cats in households	Number of healthy cats tested	Initial test of healthy cats FeLV results		Initial infection rate	Number of healthy cats removed	Second test* of healthy cats FeLV results		Number of healthy cats which became secondarily† infected	Secondary infection rate of healthy cats
				Infected	Uninfected			Infected	Uninfected		
Households where FeLV-infected healthy cats were removed	51	847	817	190	657	22.4%	190	3	654	3	0.46%
Households where FeLV-infected healthy cats were not removed	25	413	413	129	284	31.2%	0	184	229	55	19.3%

*The second FeLV test was performed at least 3 months after the initial FeLV test.
†A secondarily infected cat is one which was FeLV uninfected in the initial test but was found to be infected in the second test.

Table 3 Summary of disease development in household groups

Household groups	Number of households	Number of initial test FeLV-uninfected cats	Number of healthy cats which became secondarily infected	Disease development in secondarily* FeLV-infected healthy cats						Natural mortality rate in first test FeLV-uninfected§ healthy cats	Number of cats which died naturally	Natural mortality rate in secondarily FeLV-infected healthy cats
				Lymphosarcoma	Other FeLV† caused diseases	Other non-FeLV‡ caused diseases	Number of cats which died naturally	Alive	Euthanised			
Households where FeLV-infected healthy cats were removed	51	657	3	—	—	—	—	3	—	—	—	—
Households where FeLV-infected healthy cats were not removed	25	284	55	7	6	11	24	22	9	8.5%	24	52%

*A secondarily infected cat is one which was FeLV uninfected in the initial test but was found to be infected in the second test.
†4 cats with FeLV non-regenerative anaemia; 2 cats with the panleukopaenia-like syndrome.
‡3 cats with feline infectious peritonitis; 8 other diseases—these diseases occur frequently in FeLV-infected cats due to the immunosuppressive effects of the virus.
§These cats subsequently became secondarily infected with FeLV.

owners implemented the FeLV test and removal programme. A total of 847 cats were tested for FeLV in the 51 households in which the programme was implemented (Table 2). Of these 847 cats, 190 cats were found to be infected in the initial FeLV test (an initial infection rate of 22.4%) and were immediately removed from contact with the remaining 657 uninfected cats. Only 3 of these 657 uninfected healthy cats were found to be infected in the second test. In the 3-month period between the two IFA tests, 99.54% of the initially uninfected cats therefore remained uninfected (a secondary infection rate of 0.46%).

In the 25 households where the FeLV-infected healthy cats were not removed, and thus remained in continual contact with other cats in the households, a total of 413 cats were tested for FeLV and 129 were found to be infected in the initial test (an initial infection rate of 31.2%). Of the remaining 284 uninfected healthy cats in these households, 55 were found to be infected in the second test (a secondary infection rate of 19.3%) (Table 2). Thus only 80.7% of the initially uninfected cats remained uninfected in the 3-month period between the two tests. The secondary FeLV infection rate in the households in which the FeLV test and removal programme was not implemented was 42 times greater than that in households in which the programme was implemented. This difference is highly significant ($P \leqslant 0.0001$) by the χ^2 test. Thus the natural contagious spread of FeLV between cats was effectively prevented by the FeLV test and removal programme.

We have reported previously that FeLV-infected cats have a significantly higher chance of developing one of the FeLV-related diseases[3] and a much higher mortality rate than uninfected cats[17]. There was a marked difference in the occurrence of the disease and the mortality rate of cats living in the two household groups. The development of FeLV-related diseases was prevented in healthy cats living in the 51 households in which the test and removal programme was implemented. In contrast, in the 25 households where the programme was not implemented, 7 cats have developed LSA, 4 cats have developed FeLV non-regenerative anaemia and 13 cats have developed other FeLV-associated diseases within the 2-yr observation period (Table 3).

The natural mortality rate for the 3 healthy initially uninfected cats which became secondarily infected in those households in which the programme was implemented was not determined since the cats were euthanised immediately after they were found to be infected and thus did not have a chance to develop disease. In the 25 households in which the programme was not implemented 24 of the 55 secondarily infected cats subsequently died resulting in a mortality rate of 52%. These 24 deaths represent a natural mortality rate of 8.5% of the 284 initially FeLV-uninfected healthy cats (Table 3).

Some healthy cats living in households where the control programme was not implemented remained uninfected even though they were continually exposed to viraemic cats. To ensure that the test and removal programme, rather than FeLV neutralising antibody, was responsible for the protection of uninfected cats, cats living in selected households which implemented the programme were examined for neutralising antibody. Forty-one per cent of these cats tested had protective ($\geqslant 1:10$) neutralising antibody titres. Fifty-nine per cent of the cats thus had non-protective antibody titres and were susceptible to FeLV infection. Because of the implementation of the test and removal programme, however, these susceptible cats were not continuously exposed to FeLV and thus remained uninfected and did not develop any FeLV related diseases.

Pet cats of all ages are susceptible to FeLV infection in their natural household environments. The median age when FeLV was first detected in 49 of the secondarily infected pet cats in our study was 24.0 months. The median age at which these cats were last tested and found to be uninfected was 18.0 months. Therefore, between 18 and 24 months these adult pet cats became infected with FeLV in their household environments.

The FeLV test and removal programme is currently being used by many veterinarians to protect FeLV-uninfected cats

from FeLV infection and disease development[16]. The diseases caused by, or associated with, FeLV can be prevented by the test and removal programme. This is significant since diseases caused by and associated with FeLV are probably the most common killer of pet cats.

The results obtained by identifying and removing the healthy inapparent FeLV-infected carrier cats show for the first time that it is possible to prevent the contagious spread of a mammalian oncornavirus in the natural environment. FeLV and the diseases it causes may ultimately be controlled by a combination of the test and removal programme and vaccination.

Strain differences in the autoimmune response of mice to acetylcholine receptors

EXPERIMENTAL autoimmune myasthenia gravis (EAMG) has been induced in rabbits[1-4] guinea pigs[5,6] rats[4,6] and monkeys[7] by injection of the acetylcholine receptor (AChR) isolated from electric fish. The experimental disease, together with the demonstration of humoral[8-10] and cellular[11] immune responses to AChR in patients with myasthenia gravis (MG), verifies hypotheses[12,13] about the immunopharmacological block of AChR in MG. An experimental model disease in mice is needed for studies of the genetic aspects of MG and the role of the thymus as a specific antigen target, and as a source for immunocompetent helper and suppressor cells. We describe here the induction of EAMG in several inbred strains of mice and demonstrate different susceptibility to the disease in strains representing different haplotypes of the major histocompatibility complex (H-2). We describe some humoral and cellular aspects of the disease and demonstrate that in a susceptible mouse strain both humoral and cellular immune response to self-AChR are elicited. Finally we show that AChR behaves as a thymus-dependent antigen.

Mice were injected twice with a 9-week interval with 10 μg of purified *Torpedo californica* AChR (specific activity 10 nmol of toxin per mg protein) per mouse. The immunogen was emulsified in complete Freund's adjuvant (CFA) and injections were made into the footpads. Ten days or more after the second injection clinical signs of EAMG were observed in mice of the following strains: A/J and B10.A with the H-2ᵃ haplotype, C57BL/6, C3H.SW and CWB with H-2ᵇ, BALB/c and DBA/2 with H-2ᵈ, AKR/Cu and CKB with H-2ᵏ. The disease was not found in any mice with H-2ᵠ and H-2ˢ haplotypes (Table 1). The sick mice suffered from weight loss and exhibited signs of fatigue, hypoactivity, ruffled fur, paralysis of the limbs and motor impairment, which was accentuated by exercise. Their heads were sinking and their backs were exaggeratedly humped. Severely sick animals died from the disease, whereas in some cases the disease seemed to be transient.

Table 1 EAMG incidence and antibody titres against AChR in different strains of mice

Strain	H-2 Haplotype	log₂ Haemagglutination titre			Animals with clinical signs of EAMG
		1 °C day 21	1 °C day 63	2 °C day 8	
A/J	a	8.2	13.5	20.3	1/5
B10.A	a	7.5	11.2	20.0	2/5
C57BL/6	b	8.0	11.8	18.9	8/12
C3H.SW	b	7.5	11.0	19.3	2/5
CWB	b	7.5	11.5	19.6	2/10
BALB/c	d	7.5	11.2	19.8	2/5
DBA/2	d	8.0	11.0	20.2	2/6
C3H/Hej	k	7.5	12.0	18.5	2/5
CKB	k	7.6	11.3	20.0	2/6
AKR/Cu	k	7.8	11.4	19.0	6/6
DBA/1	q	7.2	11.3	20.2	0/6
SWR	q	8.2	11.4	20.6	0/6
SJL/J	s	8.0	11.8	21.0	0/6
ASW	s	7.3	11.7	20.6	0/6

Antibody titres were determined by micropassive-haemagglutination technique. Formalinised sheep red blood cells were coated with *Torpedo* AChR (100 μg per ml packed cells) by means of tannic acid.

The symptoms of mice with EAMG were reversed temporarily soon after intravenous injection of 5 μg of edrophonium chloride (Tensilon). In particular there was improvement of motor performance such as gripping and walking. Further pharmacological evidence for a physiological aberration in neuromuscular transmission in mice with EAMG was obtained from a curare ((+)-tubocurarine) test[14]. All the AChR-injected mice of strains in which symptoms of EAMG were observed, including individual mice which did not exhibit symptoms, had a higher sensitivity to curare than did the resistant strains. For example, injection of 0.6 nmol of curare intravenously was lethal for the AChR-injected C57BL/6 mice, tested 5 months after the first injection, whereas 2.4 nmol was required to kill

Table 2 Incorporation of tritiated thymidine by cultures of lymph node cells from C57BL/6 mice sensitised with AChR

Antigen added to sensitised lymph node cells (μg per culture)		Stimulation index*	
		day 10	day 42
AChR	(0.50)	9.24	5.16
	(0.25)	10.07	7.14
Mouse (C57BL/6)	(5.0)	4.30	Not done
muscle extract	(2.5)	2.58	Not done
Rabbit muscle extract	(5.0)	6.50	8.66
Lysozyme	(2.0)	1.16	0.88

Microculture lymphocyte transformation technique was used according to the method described by Oppenheim *et al.*[15]. Mice were injected with 10 μg of AChR in CFA in the footpads 10 or 42 d before the experiments.
*Ratio of c.p.m. of experimental to control cultures; average of five experiments.

Fig. 1 Electromyographs from myasthenic and normal C57BL/6 mice. Supramaximal tetanic stimulation was applied to the sciatic nerve at a frequency of 20 per s with rectangular pulses of 0.1 ms duration and 0.75–1.5 V amplitude. The evoked compound muscle action potential was recorded with a coaxial needle electrode embedded in the calf muscle by an HP electromyograph. *a*, Myasthenic mouse; *b*, control mouse.

Table 3 Antibody response to AChR in an adoptive cell transfer experiment in C57BL/6 mice

Group no.	Cells transferred into lethally-irradiated mice	AChR injected	log₂ Haemagglutination titre* day 7†	day 12	day 18
(1)	Normal spleen cells (30 × 10⁶)	10 µg in CFA	2.25	5.0	6.37
(2)	Normal spleen cells treated with ATS‡ (30 × 10⁶)	10 µg in CFA	1.20	1.66	1.75
(3)	Primed spleen cells§ (30 × 10⁶)	10 µg in CFA	ND	13.0	14.75
(4)	Primed spleen cells treated with ATS (30 × 10⁶)	10 µg in CFA	ND	1.70	1.88

Cell-transfer experiments into lethally irradiated mice (800 rad ⁶⁰Co whole-body irradiation) were performed in a procedure similar to that described by McDevitt and Tyan[17]. ND, Not done.
*Average titre of 10–25 mice.
†Days after injection of AChR.
‡Anti-thymocytic serum.
§Cells obtained from mice injected with 10 µg of AChR in CFA 3 weeks earlier.

normal C57BL/6 mice. On the other hand, AChR-injected SWR and DBA/1 mice (H-2�q) as well as SJL/J and ASW mice (H-2ˢ) which showed no symptoms were not significantly more sensitive to curare than normal siblings which had not received antigen. Neurophysiological studies of C57BL/6 mice, made with an HP electromyograph revealed a decrease in amplitude during repetitive nerve stimulation in sick mice (Fig. 1a) and a normal response in control animals (Fig. 1b). Moreover, AChR-injected C57BL/6 mice which had no symptoms also showed a decremental response to repetitive nerve stimulation. The decremental electromyographic response as well as the pharmacological effects of Tensilon and curare are common criteria for verifying the neuromuscular block in MG.

The autoimmune response against self-AChR in C57BL/6 mice injected with *Torpedo* AChR was demonstrated by cellular and humoral reactivity towards syngeneic muscle extracts. Cellular sensitivity was tested by the *in vitro* lymphocyte transformation technique. As Table 2 shows, lymph node cells of mice injected once with *Torpedo* AChR were stimulated *in vitro* when incubated with the immunogen, as well as with xenogeneic (rabbit) and syngeneic (C57BL/6) muscle extracts. Humoral autoimmune response was demonstrated by the ability of mouse anti-AChR sera to bind to syngeneic AChR. An AChR-rich fraction was prepared from C57BL/6 mouse muscle, by solubilisation with Triton in a procedure similar to that described by Lindstrom *et al.*[16] for the preparation of rat muscle extract. AChR in the extract was labelled with ¹²⁵I-bungarotoxin and the binding of labelled receptor to mouse antiserum was measured by radioimmunoassay. Sera from C57BL/6 mice immunised with *Torpedo* AChR bound, per ml of serum, an amount of mouse AChR corresponding to 0.35 pmol of toxin-binding sites.

Humoral immune response towards *Torpedo* AChR in the injected mice was determined using the micropassive-haemagglutination technique (Table 1). Significant titres of antibodies against AChR were observed in the mouse sera 3 weeks after a single immunisation. The antibody levels increased during the following 6 weeks and an additional significant increase was observed 8 d after the booster. No correlation between the antibody titres and incidence of the disease was found, as mice of all tested strains gave similar antibody titres (Table 1). It is possible, however, that there are differences in the specificity of the antibodies, especially as AChR is a high molecular-weight immunogen which presumably contains multiple potential immuno-potent determinants. The susceptibility to EAMG may thus be determined by a genetically controlled ability to respond to a specific determinant (or determinants), not necessarily identical with the immunogenic determinants. Alternatively, circulating anti-AChR may not have a major role in the pathogenesis of EAMG. The mouse model disease which has a great advantage because of the availability of many inbred strains, together with immunochemical analysis of the AChR molecule can be helpful in the elucidation of this question.

The humoral response against AChR is T-cell dependent as was shown in adoptive transfer experiments (Table 3). It seems that T cells are required both for a primary and secondary immune response. Lennon *et al.*[18] have previously demonstrated in rats that thymus-derived lymphocytes are required for the induction of EAMG and antibody to AChR. It should be interesting to try to dissociate the role of the thymus as a source of T-helping and T-suppressing cells from the possible specific role of the thymus as an antigenically cross reacting target with AChR[19].

We have demonstrated the induction of EAMG in mice after two injections of *Torpedo californica* AChR. The clinical, pharmacological, electrophysiological and immunological findings in mice with EAMG closely parallel those in patients suffering from MG as well as in other animals with EAMG. Mice with EAMG were shown to react with self-AChR, probably as a result of breakdown of tolerance. Strains seem to vary in their susceptibility to the experimental disease. We do not know, however, whether there is a similar pattern for susceptibility to spontaneous disease, and whether such a pattern is genetically controlled.

We thank Drs O. Abramsky, A. Aharonov and E. Mozes for discussions.

Selective IgA deficiency in chickens with spontaneous autoimmune thyroiditis

SELECTIVE IgA deficiency is believed to be the commonest form of human immunodeficiency disease, and occurs with a frequency of between 1:500 and 1:700 in random populations[1,2]. Although the isolated deficiency is often considered non-pathological, there is clinical and laboratory evidence that IgA-deficient individuals suffer more sinopulmonary infection and autoimmune and gastrointestinal disorders[3,4]. Family studies have suggested a genetic factor but no defined inheritance patterns have been established[4,5]. The chicken model has been used for a number of years in our laboratory to study the ontogeny of immunoglobulin class development[6]. Surgical bursectomy at hatching[7,8], treatment of chick embryos with specific antisera[7,9-11] and combined neonatal bursectomy–thymectomy[12] can result in depressed levels of IgA. This report describes recent observations of a selective IgA-deficiency that spontaneously occurs in the Obese strain (OS) of White Leghorn chickens. The OS chickens develop spontaneous autoimmune thyroiditis (SAT) at several weeks of age[13]. Clinical hypothyroidism is

been reported that selective IgA deficiency in humans is often associated with increased amounts of serum IgM as well as increased number of plasma cells containing IgM in the laminia propria of the small intestine, indicating that a compensatory mechanism may occur in some individuals[3].

The relationship of autoimmune disease in humans to selective IgA deficiency has not been determined. While the majority of patients with autoimmune disorders have normal levels of IgA, those patients with the IgA deficiency have an increased incidence of abnormal κ/λ ratio, elevated levels of IgG and/or IgM, and serum 7S IgM[4]. Furthermore, those individuals who lack IgA have normal or increased numbers of IgA-bearing lymphocytes in the peripheral blood[20]. These observations suggest that the abnormality in the immune response occurs in the latter stages of cell maturation and results in the absence of IgA-secreting plasma cells. With the advent of an animal model for spontaneous IgA deficiency it is now possible to study the genetic and cellular events responsible for this deficiency. Indeed, preliminary experiments in our laboratory have already suggested a genetic relationship between IgA deficiency and alleles at the major histocompatibility locus in chickens.

Table 1 Serum immunoglobulin concentrations in OS and CS chickens*

Line	Age	Number tested	IgY(mg %)† ±s.d.	IgM(mg %) ±s.d.	IgA(mg %) ±s.d.	Number with undetectable IgA	Total number with <10 mg % IgA
OS	6 weeks	12	228±2.9	146±1.3	5.57±3.9	4	7
CS	6 weeks	18	254±2.0	93.4±1.3	24.5±1.3	0	0
OS	1 yr	30	456±1.7	201±1.5	16.5±4.4	5	8
CS	1 yr	24	599±1.3	89.3±2.2	27.6±2.1	0	1

*Minimum sensitivity of the radial immunodiffusion assay is 2.0 mg % for IgY and 3.0 mg % for IgM and IgA.
†Serum immunoglobulin levels are presented as geometric mean. Analyses were performed on $\log_{10}$ transformed data.

observed and high titres of circulating as well as bound anti-thyroglobulin antibodies can be detected[14]. The OS chickens were initially derived from the Cornell C-strain which reveals a 1% incidence of SAT. Selective breeding of CS birds, which showed phenotypic symptoms of hypothyroidism, resulted in the OS of which now, in generations 16 and 17, show 96% SAT. The histological and serological features in OS chickens make it a reasonable animal model to study Hashimoto's thyroiditis, an autoimmune disorder in humans[15].

Serum immunoglobulins IgY (ref. 16), IgM, and IgA were quantified by radial immunodiffusion in Agarose gel with heavy chain-specific antisera and reference standards prepared in our laboratory[17]. This technique is conventionally used to diagnose selective IgA deficiency in humans[18]. Both systems can detect IgA concentrations as low as 2–3 mg %.

In Table 1 the serum immunoglobulin concentrations of a random population of 6-week and 1-yr-old OS and CS chickens are presented. Serum IgA concentrations were markedly decreased in OS chickens with a mean concentration of 5.6 mg % in 6-week-old birds and 16.5 mg % in 1-yr-old birds. Although many of these OS birds had normal levels of IgA, 33% (4 of 12) 6-week-old birds and 16% (5 of 30) 1-yr-old birds had undetectable levels of IgA (<3.0 mg %). In contrast, only one CS bird had an IgA level of less than 10 mg % and none had undetectable levels of IgA. In addition to the isolated IgA deficiency in OS chickens, an increase in serum IgM levels were noted. It was observed, however, that the IgA-deficient birds did not necessarily have a selective increase in IgM, but rather the increased IgM was present throughout the entire OS population. This is consistent with the increased number of IgM-bearing B-cells found in OS chickens[19]. It has previously

OS strain was developed and is maintained by the Department of Poultry Science at Cornell University. Dr Luster is a recipient of a USPHS fellowship from the NIAID.

Transformation of human lymphocytes by Epstein-Barr virus is inhibited by phosphonoacetic acid

PHOSPHONOACETIC acid (PAA) is an inhibitor of herpes simplex virus and of several other herpes viruses. It acts as a specific inhibitor of two viral DNA polymerases, those of herpes simplex and of Marek's disease (a herpes-induced leukaemia in chickens)[1,2]. We have used PAA as a probe to investigate the possible existence of a virus-directed DNA polymerase and its role in replication of viral genomes during the transformation and proliferation of normal human peripheral lymphocytes induced by Epstein-Barr virus (EBV), which is a herpes virus closely associated with the development of several neoplasms in man.

Synthesis of the EBV capsid antigen (VCA), but not of the early antigen (EA), is dependent on DNA synthesis[3]. Moreover, EBV producer lines cease synthesis of VCA and biologically active virus after several days of treatment with PAA at concentrations which do not have a measurable effect on cellular growth, cellular DNA synthesis or expression of either EA or the EBV nuclear antigen (EBNA)[4,5]. The average number of copies of the viral genome per cell also decreases in these conditions because of the inhibition of productive viral DNA synthesis. Replication of latent viral DNA seems to be unaffected by PAA[5,6]. Although no EBV-specific DNA polymerase has been isolated, these data suggest the existence of such an enzyme.

Little is known about the events by which EBV causes resting normal peripheral lymphocytes to transform and proliferate. The only two indicators of transformation are an increase in cellular DNA synthesis[7,8] and the appearance of EBNA several days after infection[9]. Because of the limitations of material and available techniques, information about the behaviour of the viral DNA during infection is limited. Replication of the viral DNA after infection is suggested, however, by the presence of multiple copies of the viral genome in lymphoblastoid cell lines produced by *in vitro* infection with EBV[10].

EBV transforms only the B-cell population of peripheral blood lymphocytes. Therefore, purified B-cell populations from normal adults were used to study DNA synthesis after infection with EBV. Use of purified B cells greatly decreases the background level of DNA synthesis by untransformed cells and provides a much more sensitive measure of virus-induced DNA synthesis than does the use of unfractionated cells. This method is at least as sensitive as the more commonly used cord blood lymphocytes and a full account will be published elsewhere. Briefly, blood was drawn from normal healthy adult donors into heparinised syringes and mixed 1 : 1 with Hanks' balanced salt solution. The peripheral lymphocytes were purified by centrifuging over Ficoll-Hypaque[11]. The lymphocytes at the interface were washed with medium (RPMI 1640 plus penicillin (100 U ml⁻¹), streptomycin (100 µg ml⁻¹), glutamine (300 µg ml⁻¹) and 5% foetal calf serum) and passed over an immunoabsorbent column of goat (anti-human Fab') antibody coupled to Sephadex G-200 (ref. 12). The B-cell population was bound to the column and was eluted with a 1% solution of human γ globulin and then twice washed with medium. This population is > 95% B cells as judged by labelling with fluorescent rabbit (anti-human Fab') antibody.

The rate of DNA synthesis by normal peripheral B lymphocytes cultured in the presence of various concentrations of PAA and assayed 6–7 d after addition of the transforming strain of EBV from the supernatant of the B95-8 marmoset lymphoblast culture is shown in Fig. 1.

There was demonstrable inhibition of DNA synthesis with as little as 12.5 µg ml⁻¹, with 50% inhibition at 100 µg ml⁻¹ and complete inhibition at 200 µg ml⁻¹. As a control, the effect of PAA on DNA synthesis in B lymphocytes stimulated by phytohaemagglutinin or pokeweed mitogen was studied. There was no inhibition up to a PAA concentration of 100 µg ml⁻¹ and only 30% inhibition at 200 µg ml⁻¹.

Consistent with the above observations of DNA synthesis, PAA at 100–200 µg ml⁻¹ was sufficient to inhibit completely the outgrowth of B-cell cultures infected with the B95-8 strain and observed for up to 1 month after infection, compared with controls which grew out after 12 d (Fig. 2).

The inhibitor did not act directly on the virus, however,
Fig. 1 Effect of PAA on DNA synthesis of normal peripheral B lymphocytes transformed by EBV or mitogens. Purified B cells were suspended at 2×10^6 ml⁻¹ in RPMI 1640 medium supplemented with 20% foetal calf serum, and 0.1-ml samples were added to Wells of a Linbro Micro Test II plate. EBV (see below), PHA (Burroughs Wellcome final concentration 0.25 µg ml⁻¹) and pokeweed mitogen (Gibco, final concentration 40 µg ml⁻¹) were diluted appropriately with the same medium and added in 0.1 ml to make a final volume of 0.2 ml per well. PAA, at appropriate dilutions, was added when required in a volume of 3–5 µl by means of an automatic delivery Hamilton syringe. All experiments were set up in triplicate. The cells were incubated at 37 °C in a humidified, 5% CO_2 atmosphere. After 6 d the cells were pulsed overnight with 50 µl of medium containing ³H-thymidine (New England Nuclear, 2 Ci mmol⁻¹, 2 µCi ml⁻¹). The cells were collected on glass fibre filters, washed repeatedly with saline followed by 5% ice-cold trichloroacetic acid and 95% ice-cold ethanol. The filters were dried and the remaining radioactivity was assessed by addition of 5 ml of Liquifluor scintillation fluid and counting. The experimental results are expressed as

$$\frac{\text{c.p.m. in experimental}}{\text{c.p.m. in positive control}} \times 100\%$$

The c.p.m. in the positive controls (EBV or mitogen-added but no PAA) were EBV 1:10 (●)=6,810; 1:50 (□)=6.490; 1:100 (■)=1,510; PHA (○)=6,764; pokeweed mitogen (△)=4,774. Broken and unbroken lines represent B cells from different individuals with unstimulated incorporations of 105 and 141 c.p.m. respectively. The B95-8 EBV concentrates used in these experiments were provided by Dr K. A. Traul of Pfizer Inc. lot no. 3373-11, TCID₅₀ 10⁶·⁵ U ml⁻¹ by induction of EBNA in cord blood, electron microscopic count 4×10^8 viral particles per ml.
Fig. 2 Appearance of cultures infected with EBV to which PAA had not (*a*) or had (*b*) been added. Parallel cultures were infected with a supernatant from the B95-8 marmoset cell line, at a dilution of 1:10. Every 3–4 d half the culture medium was replaced with fresh medium. For full experimental details, see legend to Fig. 1a, Control culture infected with EBV alone and photographed 12–15 d after infection. After this time it is necessary to transfer the cells to larger wells to maintain them. Growth, as illustrated, occurred in all of 33 wells to which virus was added. *b*, Culture infected with EBV and maintained in the presence of PAA 100 μg ml⁻¹ photographed 30 d after infection. At no time was an increase in cell number observed in any of 33 wells.

for preincubation with PAA for up to 6 h at 37 °C did not affect the activity of the virus in stimulating DNA synthesis after removal of the inhibitor (data not shown). Furthermore, expression of at least two viral functions was unaffected insofar as PAA up to 200 μg ml⁻¹ did not affect induction of EBNA in the peripheral B lymphocytes, nor did it affect induction of EA in the Raji cell line by the superinfecting strain of EBV from the P3HR-1 cell line (Table 1). Although PAA does not inhibit induction of EBNA in either adult peripheral B lymphocytes or those from cord blood, it is inhibited by cytosine arabinoside which blocks all DNA synthesis (I. Ernberg and G. Klein, personal communication). Both PAA and cytosine arabinoside are ineffective, however, in preventing EBNA induction during conversion of the EBV-negative lymphoblastoid line Ramos

into its EBV-positive derivatives[13]. This suggests that cytosine arabinoside does not act directly on EBNA production but is effective in the transformation experiments because it prevents blastogenesis, and that once the cells have undergone blastogenesis, EBNA may be induced without DNA synthesis.

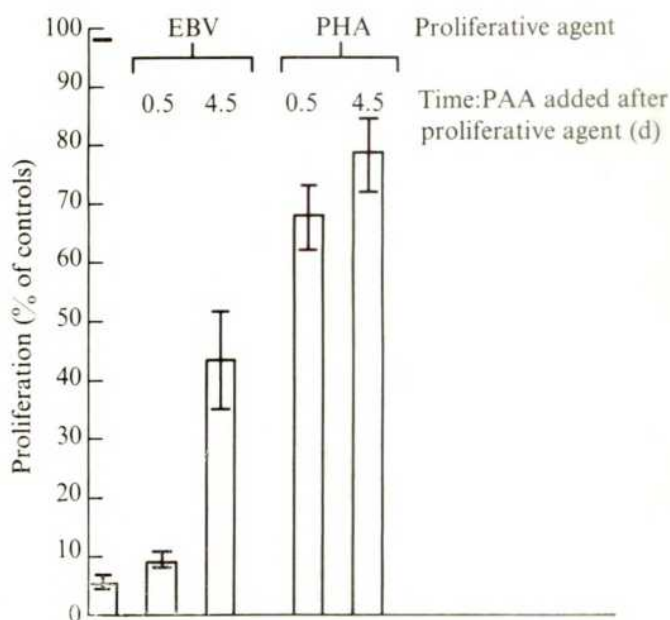
It is interesting that with PAA at 100–200 μg ml⁻¹, cellular DNA synthesis stimulated by mitogens and EBNA induction were unaffected, whereas the transformation and outgrowth of EBV-infected cultures was inhibited. This implies that induction of EBNA is not sufficient to cause


Fig. 4 Effect of adding PAA (200 μg ml⁻¹) 0.5 and 4.5 d after stimulation of DNA synthesis by EBV or PHA. Normal peripheral B lymphocytes were treated with EBV (dilution 1:10) or PHA as described in the legend to Fig. 1. PAA was added in 3–5 μl either 0.5 d or 4.5 d after cultures were set up. The rate of DNA synthesis was assayed 6 d after cultures were infected. Each column is the result of averaging the results obtained using cells from six different donors and the bars represent 1 s.d. The positive controls varied between 700 and 3,700 c.p.m. with EBV and 2,200 to 2,600 with PHA. A culture not treated with virus is shown in the left column.

Fig. 3 Effect of PAA, added at various times after infection, on the rate of EBV-stimulated DNA synthesis. Purified human peripheral B lymphocytes were set up in culture in the presence of a 1:10 dilution of EBV as described in the legend to Fig. 1. PAA was added at various times in a volume of 3–5 μl to give the appropriate final concentration from an automatic delivery Hamilton syringe. The cells were assayed for DNA synthesis, as described in the legend to Fig. 1, 9 d after infection. ●, PAA final concentration 50 μg ml⁻¹; ○, PAA concentration 200 μg ml⁻¹. The c.p.m. in positive control = 1,976.

cells to proliferate logarithmically even when the cellular DNA synthetic system is intact.

The nature of inhibition of DNA synthesis by PAA after EBV infection was studied further by adding the inhibitor to different cultures at various times after the virus. The rate of DNA synthesis was measured 9 d after infection. PAA was effective when added up to 3 d after infection but thereafter effectiveness decreased (Fig. 3). The effectiveness of PAA when added many hours after the virus confirms the observation that PAA does not act on the viral particle directly and implies also that it does not affect penetration of the cell by the virus. The decrease in effectiveness of PAA could have been a result of its slow incorporation; it took about 5 d to reach effective levels. This was ruled out, however, by the observation that the decrease in sensitivity occurred at the same time whether the cells were collected for assay 7 or 9 d after infection.

The decrease in the sensitivity of EBV-stimulated DNA synthesis to PAA is specific, as shown when PAA at 200 μg ml⁻¹ was added to cultures 0.5 or 4.5 d after infection with EBV or stimulation with PHA (Fig. 4). There was little change in the sensitivity of PHA-stimulated cellular DNA synthesis with various times of addition, synthesis being inhibited by 20–30% in both cases, perhaps because of
Fig. 5 Time course of DNA synthesis in lymphocytes infected with EBV. Parallel cultures of uninfected and virus-infected (by additions of supernatant solution from a culture of B95-8 cells diluted 1:10) cells were set up in triplicate at various times. Thereafter, the rate of DNA synthesis was assayed as before, except the cells were pulsed for 4 h. The specific rate of DNA synthesis was calculated by subtracting the value measured for the uninfected cultures from that obtained with the infected cultures. For full experimental details, see legend to Fig. 1.

Table 1 Effect of PAA on induction of EBNA in normal peripheral B lymphocytes and EA in the Raji lymphoblastoid cell line

| | | (PAA) μg ml^{-1} | | |
	no virus	0	100	200
EBNA+ve cells	—	+	ND	+
% EA+ve cells*	<0.25	5.1	5.8	4.8

To measure EBNA induction, 5×10^6–10×10^6 B lymphocytes were infected with B95-8 virus in the usual way (see legend to Fig. 1); 3–4 d later the cells were collected and stained for EBNA by the anticomplement immunofluorescent technique[14]. EA induction by P3HR-1 EBV in the Raji cell line was tested as described by Klein *et al.*[15]. Anti-EA antisera for the direct fluorescence test were provided by Dr G. Klein.
*Average of duplicates, about 2,000 cells each were counted.
ND, Not done; +, the same level of positive cells as in the control, approximately 5%.

is then kept constant—it replicates with the cellular DNA. The amplification may conceivably be a prerequisite for integration of one or more EBV genomes into the cellular DNA synthetic system, functionally and perhaps also physically. Alternatively, replication could be required simply for the transcription and translation of one or more genes required for transformation.

If a PAA-sensitive, virally induced DNA polymerase (by analogy with herpes simplex[1] and the Marek's disease[2] DNA polymerase) is required for gene amplification before integration, then it follows that viral DNA synthesis is required for true cellular proliferation. At the simplest level, the single cell infected with EBV in the presence of PAA may be transformed, able to express EBNA and to divide indefinitely. It carries only one non-replicating copy of the viral genome, however, and therefore can generate only one daughter cell carrying and expressing the viral genome and able to divide. Thus, cultures infected with EBV in the presence of PAA may contain transformed and dividing cells, but the cell number per culture would not increase exponentially and inhibition of proliferation would be observed.

inhibition of a host DNA polymerase which is reported to be sensitive to PAA (J. Liversidge and W. Benz, personal communication). The EBV-stimulated DNA synthesis was completely inhibited when PAA was added early after infection but only about 50% inhibited when added at 4.5 d.

The most likely explanation of these results is that there is a process which is sensitive to PAA and is required for the initiation of cellular proliferation. This process occurs during the first 3–4 d after infection, at which time cellular DNA synthesis begins and apparent PAA sensitivity decreases. This hypothesis is supported by the observation that a considerable increase in cellular DNA synthesis occurs at 3–4 d after EBV infection (Fig. 5), precisely the time after which addition of PAA is no longer effective in inhibiting transformation.

In conclusion, the data presented here indicate the existence of a PAA-sensitive event, which is necessary for transformation and unlimited proliferation of normal peripheral B lymphocytes. PAA does not, however, act directly on the virion nor does it block penetration of the cell by the virus or the subsequent expression of EBNA. It is known that cell lines produced by *in vitro* infection with EBV contain 10–15 copies of the viral genome per cell[10]. It seems likely therefore that some amplification of the viral genome occurs after infection. This amplification must cease after a short time and the viral genome number

Complement-dependent adherence of mast cells to schistosomula

MAST cells are thought to have a major role in the host response to parasitic helminths. Infection with these organisms is often accompanied by anaphylactic hypersensitivity and mast cell infiltration[1]. In several experimental models, host resistance to helminth infection has been shown to be dramatically suppressed as a result of mast cell depletion[1]. For example, after injection with reserpine, laboratory mice are unable to mount a cutaneous inflammatory response against *Schistosoma mansoni* (A.S.,

P. W. Askenase, S. McIntyre and F. von Lichtenberg, un-published) and after pretreatment with compound 48/80 can no longer immunologically reject challenge infections of this parasite[2]. Interactions between mast cells and helminths have generally been attributed to soluble antigens released into tissue fluids. Described here is a series of *in vitro* experiments with schistosomula of *S. mansoni* which demonstrates that mast cells are also capable of reacting directly with parasite surfaces. This interaction appears to depend on the recognition of parasite-bound complement by receptors on the mast-cell membrane.

Schistosomula were prepared by allowing *S. mansoni* cercariae to penetrate rat skin *in vitro*[3], and were stored overnight at 4 °C before use[4]. Mast cells were purified from peritoneal washouts of uninfected male Charles River CD (Caesarean derived) rats (175–300 g) by centrifugation over Metrizamide (22.5%)[5]. The cells recovered from the pellet fraction were routinely found to contain a minimum of 90% mast cells as determined by toluidine-blue staining. Both schistosomula and mast cells were washed three times in HEPES-buffered Hanks' minimal essential medium (MEM) containing 1% heat-inactivated foetal calf serum (FCS) and resuspended in MEM containing 10% FCS (MEM/FCS). A serum pool obtained from CD rats 8 weeks after a primary infection[6] of 1,500 cercariae each was used as a source of anti-schistosome antibody. The immune serum was diluted in MEM/FCS and used in the assay at a final concentration of 1/20. The adherence test was carried out
Fig. 1 Photomicrograph ($\times 216$ magnification) of a typical schistosomulum after incubation with fresh immune rat serum and purified rat mast cells.

in glass tubes (6×50 mm) containing the following sequential additions: 0.1 ml of schistosomula (90–110 organisms), 0.1 ml of diluted immune serum, 0.1 ml of diluted normal rat serum (complement source), and 0.1 of mast cells (2×10^5–4×10^5 total cells). After incubation at 37 °C for 90 min, the supernatant was withdrawn from each tube and the cell–parasite sediment resuspended in 0.1 ml of MEM/FCS containing 0.01% toluidine-blue. The parasites were then examined microscopically at 80 times magnification for adhering mast cells. Organisms with more than five adherent cells were scored as positive. Each result is the average of readings on replicate assay tubes scored independently by two different observers.

Schistosomula incubated with fresh immune rat serum formed 'rosettes' with the purified mast cells (Fig. 1), each positive organisms having a coat of about 20–100 adherent, toluidine-blue-positive cells. Approximately 90% (Table 1) of the larvae in the incubation mixture reacted in this fashion. In contrast, few if any mast cells adhered to schistosomula incubated in heat-inactivated (2 h, 56 °C) immune serum (Table 1). The addition of fresh normal rat serum to the heat-treated immune serum restored its full activity, an observation which suggested that the heat-labile factor was complement

Table 1 Adherence of rat mast cells to schistosomula in the presence of rat sera

Immune rat serum	Normal rat serum	Mast cell coated organisms (%)

*Schistosomula preincubated with rat serum (1 h, 37 °C) and washed three times (with MEM/FCS) before addition of mast cells.

rather than antibody. This hypothesis was supported by a series of experiments (Table 1) in which the adherence-promoting activity of fresh normal rat serum was shown to be partially or completely abolished by the following treatments known to inactivate complement[7,8]: (1) heating for 1 h at 56 °C; (2) pre-incubation with either zymosan (15 mg ml^{-1} serum) or cobra venom factor (200 U ml^{-1} serum) for 1 h, at 37 °C; (3) the addition of EDTA (5×10^{-3} M) to the cultures. The dependence of the adherence reaction on the alternate pathway of complement[9,10] was suggested by the failure of EGTA (5×10^{-3} M)[11] to inhibit rosetting and by the reduction in activity observed after heating the normal serum at 50 °C for 30 min (ref. 9) or pretreating it with zymosan at low temperature (2 h, 17 °C)[9].

Schistosomula incubated in normal rat serum without immune serum as an antibody source were also found to bind mast
Fig. 2 Photomicrograph ($\times 224$) of a typical schistosomulum, preincubated with normal rat serum (Pool B), washed three times in MEM/FCS and stained with fluorescein-labelled rabbit antibody specifiic for rat C3 (from Cappel Laboratories). No evidence of staining was observed when the same organisms were treated with fluorescein-labelled rabbit antibody (Cappel) produced against rat IgG but cross reactive with rat immunoglobulins of other classes. In contrast, schistosomula preincubated with immune rat serum stained brightly (as above) with the same anti-immunoglobulin reagent.

cells, different serum pools inducing different levels of adherence (Table 1). After preincubation with normal rat serum (1 h, 37 °C) and extensive washing (with MEM/FCS), schistosomula remained highly reactive with mast cells. The activity of normal serum in promoting adherence did not seem to be due to the presence of 'natural antibodies' with specificity for schistosome surface antigens since membrane-bound rat antibodies were not detected on worms pretreated with normal serum by means of immunofluorescent staining with fluorescein-labelled antibody specific for rat immunoglobulins. In contrast the same pretreated organisms stained brightly (Fig. 2) with an immunofluorescent reagent specific for rat C3. Neither C3 staining nor mast-cell adherence was observed if EDTA $(5 \times 10^{-3}$ M) was added to the normal rat serum in the preincubation mixture.

These results suggest that the adherence of mast cells to schistosomula is dependent on the recognition of parasite-bound complement by receptors on the mast cell surface. Complement in a form suitable for recognition by mast cells is acquired by the worms either as a consequence of the reaction of antibody at the parasite's surface or, in the absence of antibody, by direct fixation. Previous studies have indicated that cercariae of *S. mansoni* possess an alternative pathway-dependent complement (C3)-activating system[12]. The retention by schitosomsula of a similar complement-activating mechanism after conversion from the cercarial stage of the life cycle would explain their behaviour in the experiments reported here.

An important question raised by the mast cell–schistosomulum adherence phenomenon concerns the nature of the receptors on the mast-cell surface involved in the recognition of the parasite–complement complex. Rat mast cells have been shown to respond to the anaphylatoxins, C3a and C5a[13]. Since both complement fragments are normally released in the fluid phase and are extremely labile[13], it is unlikely that the adherence reaction involves receptors for these molecules. An alternative hypothesis is that mast cells, in common with platelets, primate erythrocytes, neutrophils, monocytes, macrophages and B lymphocytes, possess receptors for surface-bound activated C3 (refs 14, 15) and that the mast cell–schistosomulum interaction is dependent on this previously unrecognised set of immune adherence receptors.

Other questions raised by the adherence phenomenon concern the effects of the interaction on the release of mediators from mast cells and on the viability of the target organisms. Experiments aimed at answering these questions are now in progress.

I thank Susan McIntyre for technical assistance. This work was supported by grants from the Edna McConnell Clark and Rockefeller Foundations.

Variable Ca sensitivity of a K-selective channel in intact red-cell membranes

THE membranes of many cells exhibit a K-selective permeability mechanism with a gating process controlled by the concentration of Ca^{2+} in the cytosol[1]. Originally described in human red cells[2], where its function still remains unknown, this or similar mechanisms[3] seem to mediate important physiological actions in other cells[4–8].

The human red blood cell remains, nevertheless, the best model for the study of the interaction between Ca and the K gating mechanism because the composition of the media on both sides of the membrane can be known and controlled better than in any other cell[10–13]. This control is achieved, however, by treatments which are known to alter considerably the Ca reactivity of Ca-transporting mechanisms[14–16]. We
Fig. 1 Steady-state Ca content of intact red cells as a function of the external Ca^{2+} concentration in the presence of the divalent cation ionophore A23187. Red cells from fresh blood or from 3–4-d-old bank blood were washed as described previously[18] and then resuspended at about 10% haematocrit in a medium containing KCl, 75 mM; Tris-HCl (pH 7.5 at 37 °C), 10 mM; NaCl, 75 mM; $MgCl_2$, 1 mM; Inosine, 10 mM; 5 μCi of ^{45}Ca, and various concentrations of $CaCl_2$ up to about 2.5 mM. The total volume of suspension was 2.25 ml. At $t = 0$, 10 μl of absolute ethanol containing 0.05 to 1 mg ml^{-1} of the ionophore (0.1 mg ml^{-1} in this experiment) were added to the suspension which was in a magnetically stirred polythene vial inside a waterbath at 37 °C. At $t = 15.5$ min, 0.1 ml of isotonic ^{42}K–KCl was added to the suspension. At 15, 16, 16.5, 17, 18, 20, 25 and 30 min, 0.1 ml samples were placed in 1.5-ml Eppendorf centrifuge tubes containing 0.4 ml of n-butylphthalate (BDH, density 1.042–1.045) and 0.9 ml of an isotonic [Na + K]-medium containing 5 mM Tris-EGTA, all at 0–1 °C. Each sample was centrifuged immediately for 10 s at 12,000g in an Eppendorf centrifuge model 3200. The cells formed a compact pellet at the bottom, retaining only about 0.1% of the original extracellular fluid as estimated using ^{45}Ca in the presence of a large excess of EGTA. The aqueous supernatant remaining on top of the oil layer was removed by aspiration and the walls of the tube cleaned with cotton swabs. The cells were lysed and the proteins precipitated with 5% trichloroacetic acid (TCA) all in the same tube. Aliquots of the TCA-supernatant were used for counting both isotopes in the same samples. ^{45}Ca was counted after ^{42}K decay. Samples for total activity and haemoglobin were taken at the end of each run. In the media used here, the haematocrit did not change during the experiments and the internal K concentration remained constant over a thousandfold change in K permeability at about 130 mmol per l cell water. The results concerning the ^{42}K fluxes are given in Fig. 2. The Ca content of the cells was calculated as the mean ±2 s.e.m. of the seven time points. The slope of this particular curve is 5.91. The fraction of ionised Ca inside the cells, as calculated from this slope according to Ferreira and Lew[18], was 0.33. This value was used to estimate the concentration of ionised Ca in the cytoplasm of the cells in the experiment of Fig. 3 and an identical procedure was applied in the experiment of Fig. 4.
Fig. 2 The rate of tracer (^{42}K) equilibration in intact red cells at different intracellular levels of Ca^{2+}. The tracer equilibration process followed first-order kinetics and was adequately described by the equation

$$R_t = R_\infty(1 - \exp(-kt))$$

where R_t and R_∞ represent the activity of ^{42}K in identical volumes of cells at time t and at equilibrium and k is the rate constant of the equilibration process. This equation can be rearranged to give

$$-\ln[1-(R_t/R_\infty)] = kt$$

The figure is a plot of $-\ln[1-(R_t/R)]$ against t during some of the Ca steady states obtained in the experiment of Fig. 4 and is meant to illustrate the method used to calculate k. Since the normal volume–area ratio of the fed red cells remained unaltered during the present experiments, the K permeability (P_K) of the red-cell membrane, can be calculated from k. When $k = 1$ h^{-1}, P_K will be between 1.5×10^{-8} and 2.1×10^{-8} cm s^{-1}. The first numerical value given on each curve corresponds to the Ca^{2+} concentration inside the corresponding cells (in µmol per l cell water).

report here the surprising finding that in the intact, minimally disturbed red cell, Ca activates the K flux with a much lower affinity than that previously found in ATP-depleted red cells or resealed ghosts[1,12,13], suggesting that the higher Ca sensitivity of these systems results from treatment-induced alterations in the reactivity of labile Ca-interacting sites.

To incorporate controlled amounts of Ca inside the cells and to keep a known and constant level of ionised Ca during the measurement of the Ca-induced K flux, we used a divalent cation ionophore, A23187 (ref. 17), and a fast resolution technique for tracer flux measurements, which we developed recently[18] to study cytoplasmic Ca buffering and Ca-pump parameters in intact cells.

Since the normal mammalian red cell is virtually free of Ca^{19}, is almost impermeable to $Ca^{15,16}$ and has a powerful Ca-extrusion pump in its membrane[14], steady states with variable internal Ca concentrations could be obtained only as a balance between active Ca extrusion and ionophore-induced leaks (Fig. 1). The membrane potential was held constant by a 'chemical clamp' method in which the steady-state external concentrations of all permeable ions are in electrochemical equilibrium with the corresponding internal ions at a pre-determined potential, about -10 mV in the present experiments. At each ionophore concentration the level of internal Ca was regulated by varying the Ca concentration in the medium, and the fraction of ionised Ca was estimated from the slope of the curve relating the total internal Ca to the external Ca^{2+} concentration when the Ca pump was saturated (see text of Fig. 1). The influx of K was estimated by measuring the rate of ^{42}K-tracer equilibration at constant internal Ca and with the total external K concentration at electrochemical equilibrium with the internal K (Fig. 2). In every case, single exponentials were obtained with all the internal K participating in the equilibration process. In the absence of Ca, the ionophore had no effect on the Na and K permeability of the membrane. The entry of Ca induced a variable increase in the K flux while at the same time it reduced the Na efflux, presumably by inhibiting the Na pump[1]. Quinine (1 mM) in the medium inhibited the Ca-dependent flux in the present experiments by about 95%, just as it inhibited the Ca-induced increase in K permeability in the absence of the ionophore[3].
Fig. 3 The rate constant of tracer (^{42}K) equilibration as a function of the internal Ca^{2+} concentration in intact red cells in the presence of a low ionophore concentration. The internal Ca^{2+} concentration and k were obtained as indicated in the legend of Figs 1 and 2 respectively. The proportion of ionophore to cells was about 10 µmol per l of cells.

Figure 3 shows the variation in the rate constant of tracer (^{42}K) equilibration as a function of the internal concentration of Ca^{2+} in intact cells exposed to a relatively low ionophore concentration. The apparent K_m for Ca^{2+} is about 1.2 mM and varied in different experiments with similar ionophore concentrations between 0.33 and 1.5 mM. If the ionophore concentration is increased by ten times or more, the kinetics of Ca activation of the K permeability are completely different (Fig. 4) and approach the pattern previously observed in metabolically depleted resealed ghosts[13]. In ATP-depleted intact cells[10] we always obtained high Ca affinity-type curves, whatever the ionophore concentration, but in such cells the maximum increase in K permeability was only half that of the same cells before depletion. All these different patterns were consistently reproducible.

The variation in Ca sensitivity cannot be attributed to Mg^{2+} since the distribution of this ion at equilibrium must have been the same in all the experiments. To investigate whether the high and low Ca affinity patterns were related to the ATP content

of the cells, we measured the intracellular levels of ATP in the various conditions in which we tested the Ca effect on the K fluxes. The addition of ionophore in the absence of Ca slightly increased the ATP content of the cells in a manner reminiscent of the effect of propranolol[20]. The additional presence of Ca stimulated ATP hydrolysis through the Ca pump and induced a rapid fall in ATP from 1 mM to about 0.55 mM followed by a slower decline, presumably because of the buffering effect of membrane-bound adenylate kinase. These effects were independent of the ionophore concentration, which makes ATP alone an unlikely source of the different kinetic patterns observed in the intact cells. It is also unlikely that the variable Ca sensitivity of the K permeability system results from a non-homogeneous distribution of Ca within the cell since the K fluxes we report here were measured simultaneously in the same cells (see legend to Fig. 1 in ref. 18) where we had previously determined a constant K_m of 1 μM for the Ca activation of the Ca pump at all ionophore concentrations.

We also investigated the effect of ionophore removal on the Ca-dependent K flux. This we could only try in intact red cells loaded with Ca if the Ca pump were inhibited, and for this reason we first depleted the cells of Mg, a necessary internal cofactor for Ca extrusion[21]. Mg extraction and Ca loading were performed in succession by preincubating the cells in the presence of ionophore (10 μmol per 1 cells) first in a medium containing 2 mM EDTA and no Ca or Mg and then in Ca-containing media in the absence of Mg and chelator. The ionophore was then removed by washing the cells eight times in Ca-free ice-cold solutions at low haematocrits (about 1 %). This simple procedure restored the normal Ca impermeability of the intact cell and, with the Ca pump arrested, the cells remained effectively resealed to Ca, losing only about 25 % of their original Ca content during the initial washes. These cells also showed a high Ca affinity pattern similar to that of the intact cells at high ionophore concentrations shown in Fig. 4.

The low Ca affinity pattern shown in Fig. 3 has never been observed before. Since the cells were disturbed least in these conditions we feel that the low affinity response is closer to the behaviour of the normal system. The high affinity pattern would then correspond to an altered reactivity to internal Ca which may or may not occur in the normal cell depending on whether the Ca sensitivity of the K permeability mechanism is or is not subject to control by cellular regulatory mechanisms. Since the maximum increase in K permeability induced by Ca is more than three orders of magnitude larger than the "ground" K permeability of the intact red cell, an increase in Ca_i^{2+} even in the micromolar range[22], may suffice to produce a functionally significant increase in K permeability. A relatively

small effect could thus account for the Ca-induced hyper-polarisation observed in amphiuma red cells[23] and perhaps also in other cells[5,8].

The heterogeneous behaviour of ATP-depleted red cell populations in relation to the Ca-induced K flux[15,23] can now be interpreted as resulting from a variable Ca affinity of the K gate. This revives the old controversy[10] about whether the depleting procedure accumulates[25] or removes[26] metabolites which control the K permeability of red-cell membranes, but now it can be reformulated more precisely in terms of the control of the Ca sensitivity of the K-gating mechanism.

Since many of the conditions in which the effect of internal Ca on the K permeability is obtained resemble those in which 1,2-diacylglycerol accumulates in the red-cell membrane, as recently shown by Allan and Michell[27], we feel tempted to suggest the possibility that 1,2-diacylglycerol, or a similar metabolite, mediates the Ca effects on the K channel. According to Allan and Michell, the rate of formation of this substance depends on the internal Ca^{2+} concentration, whereas the fast conversion to an inactive phosphatide, by the action of a diacylglycerol kinase, would depend on the intracellular level of ATP. If the Ca effect on the K permeability depends on the level of a certain intermediate, the different Ca sensitivities observed in the present experiments may merely reflect the variation in the relative rates of formation and breakdown of this intermediate in the different conditions.

Fig. 4 The rate of ^{42}K equilibration as a function of the internal Ca^{2+} concentration in intact red cells in the presence of a high ionophore concentration. The concentration of ionophore used in this experiment was 1 mg ml^{-1} in the ethanol phase. This is equivalent to a proportion of ionophore to cells of about 100 μmol per 1 of cells.
Stereospecificity of interaction of neuroleptic drugs with neurotransmitters and correlation with clinical potency

THE molecular mechanism responsible for the therapeutic activity of a drug is often suggested by the biochemical event which correlates best with clinical potency. Thus, if optical or geometrical isomers of a drug have markedly different clinical potencies, the most relevant biochemical effect should also exhibit isomeric specificity.

While numerous biochemical mechanisms have been proposed to explain the antischizophrenic action of neuroleptics, the

ability of these drugs to antagonise behavioural effects of apomorphine and amphetamine in animals correlates best with clinical potency[1]. Since apomorphine and amphetamine-induced behaviours are mediated by brain catecholamines, especially dopamine, the neuroleptics are thought to act by blocking dopamine receptors in the brain. Clinical potencies of phenothiazine neuroleptics correlate reasonably well with their ability to inhibit a dopamine-sensitive adenylate cyclase which is presumably linked to the dopamine receptor[2,3]. Because pharmacologically potent butyrophenones are relatively weak inhibitors of this cyclase and show only a partial correlation with clinical potency[4], however, it has been suggested that these drugs may only indirectly affect dopamine receptors, perhaps by blocking dopamine release[5]. The chemical similarity of butyrophenones to γ-aminobutyric acid (GABA) suggests that these agents might in some way facilitate GABA transmission in the brain[1]. Since inhibitory GABA neuronal pathways may synapse on dopamine cell bodies, facilitation of GABA effects could reduce the firing rate of dopamine neurones resulting in behaviours like those associated with dopamine receptor blockade[6].

In both clinical and animal pharmacological screening, certain neuroleptics display isomeric specificity. α-Flupenthixol and cis-thiothixene are much more potent clinically and in animals than their geometrical isomers β-flupenthixol and trans-thiothixene respectively[7,8]. Similarly (+)-butaclamol is much more potent than its optical isomer (−)-butaclamol[9]. The relative potencies of butaclamol, flupenthixol and thiothixene isomers upon the dopamine-sensitive adenylate cyclase accord with their isomeric specificity in clinical studies and pharmacological screens[10,11].

Using recently developed binding techniques to study neurotransmitter receptors directly, we have examined critically how reliably stereospecificity and correlations between clinical and biochemical effects can reveal the biochemical basis of neuroleptic drug action. The results suggest that although these criteria are valuable, they can obfuscate rather than clarify drug mechanisms if used incautiously. Of the several biochemical effects of neuroleptics, blockade of dopamine receptors best accounts for therapeutic effects of both butyrophenone and phenothiazine neuroleptics.

Synaptic receptor binding studies were conducted as previously described[12-20]. Briefly, washed crude synaptic membrane or total particulate fractions of various brain regions representing approximately 1 mg of protein were incubated in a buffered solution containing a low concentration of tritiated ligand (1–8 nM) in the presence or absence of various concentrations of the drug under study. After incubation, radioactivity bound to the membranes was separated by filtration or

centrifugation, extracted into an appropriate fluor and counted by liquid scintillation spectrometry. The amounts bound in the presence and absence of the drug were compared. The ligands used in this study and the receptor to which each binds is as follows: ³H-γ-aminobutyric acid (³H-GABA), the GABA receptor[12]; ³H-dopamine (³H-DA and ³H-haloperidol (³H-Halo), the dopamine receptor[13,14]; ³H-naloxone (³H-Nal) ³H-dihydromorphine (³H-DHM), the opiate receptor[15]; ³H-dihydroalprenolol (³H-DHA), the β-adrenergic receptor[16,21]; ³H-5-hydroxytryptamine (³H-5-HT) and ³H-lysergic acid diethylamide (³H-LSD), the 5-HT receptor[17,18]; ³H-quinuclidinyl benzilate (³H-QNB), the muscarinic cholinergic receptor[19]; and ³H-strychnine (³H-Stry), the glycine receptor[20].

Receptor binding for each ligand was assayed in the brain region containing the highest density of receptor sites or in whole brain. The highest density of dopamine receptor sites is in the corpus striatum[13,14]. Binding of ³H-strychnine to glycine is most enriched in spinal cord membranes[20]. Receptor binding for ³H-LSD, ³H-5-HT and ³H-DHA is greatest in the cerebral cortex[16-18,21]. Although there exist regional variations in opiate, GABA and muscarinic receptor binding, the characteristics of binding sites do not vary regionally and substantial activity is present in whole brain or forebrain, which were used for assays of these receptors[12,15,19].

Uptake of radioactive GABA by synaptosomes in nuclei-free sucrose homogenates of whole rat brain was assayed as previously described[22].

All radioactive agents were purchased from New England Nuclear, and all other substances were obtained from the company of origin.

There are no marked stereospecific influences of neuroleptics on receptor binding for ³H-GABA, for the opiates ³H-naloxone and ³H-dihydromorphine, for binding of ³H-strychnine to the glycine receptor, for the binding of ³H-quinuclindinyl benzilate (³H-QNB) to the muscarinic cholinergic receptors or for ³H-dihydroalprenolol (³H-DHA) binding to the β-noradrenaline receptor (Table 1). In contrast, the neuroleptic isomers are extremely potent in competing for ³H-haloperidol binding to the dopamine receptor and display striking stereospecificity. (+)-Butaclamol reduces ³H-haloperidol binding 50% at 1 nM and is more than 1,000 times as potent as (−)-butaclamol in eliciting this effect. α-Flupenthixol inhibits ³H-haloperidol binding 50% at 2 nM and is 50 times as potent as β-flupenthixol, while cis-thiothixene is 100 times more potent than trans-thiothixene in competing for ³H-haloperidol binding. These neuroleptics also demonstrate stereospecificity with respect to ³H-dopamine binding, although they are less potent in competing with this ligand. Thus, while (+)-butaclamol is less than 1% as potent in inhibiting ³H-dopamine as ³H-haloperidol

†For clinical potencies, the midpoint values of daily dose ranges[18-21] were meaned and converted to μmol kg⁻¹ assuming a human weight of 70 kg.
Six concentrations of each drug were evaluated in triplicate to obtain IC₅₀ values. Data are the mean of three determinations which varied less than 15%.

binding, it is 160 times more potent than (−)-butaclamol in competing for ^{3}H-dopamine binding. Similarly α-flupenthixol and cis-thiothixene are less than 1% as potent in inhibiting ^{3}H-dopamine as ^{3}H-haloperidol binding yet they still display stereospecificity with respect to their corresponding isomers. Interestingly flupenthixol and thiothixene are just as potent in competing for ^{3}H-QNB as for ^{3}H-dopamine binding, but they display no stereospecificity in inhibiting ^{3}H-QNB binding.

Relative potencies of numerous neuroleptics as inhibitors of ^{3}H-haloperidol binding to the dopamine receptor correlate well with clinical efficacy[14,22,24]. There is, however, a much weaker correlation of neuroleptic clinical and pharmacological potency with ^{3}H-dopamine binding, in spite of the fact that both dopamine and haloperidol presumably interact with the same receptor. The differences between interactions of ^{3}H-haloperidol and ^{3}H-dopamine with the dopamine receptor seem to stem from their labelling two different states of the dopamine receptor. Agonists are much more potent in competing for ^{3}H-dopamine than ^{3}H-haloperidol binding. Conversely, antagonists have substantially higher affinity for haloperidol than dopamine-binding sites. Thus dopamine and haloperidol respectively label discrete "agonist" and "antagonist" states of the dopamine receptor[14]. This two-state model for the dopamine receptor accords with data supporting such a model for the 5-HT, α-noradrenergic and opiate receptors[25]. One would expect pharmacological activities of antagonists to be related better to their affinities for antagonist than agonist states of the receptor, which explains the better correlation of neuroleptic clinical activity with affinity for haloperidol than for dopamine binding[22].

The binding of ^{3}H-LSD and ^{3}H-5-HT is also inhibited stereospecifically and with considerable potency by these neuroleptics. The neuroleptics display about the same potency in inhibiting ^{3}H-LSD as ^{3}H-dopamine binding as well as a similar degree of stereospecificity. Thus (+)-butaclamol is 140 times as potent as (−)-butaclamol in lowering ^{3}H-LSD binding and is about 160 times as potent as the (−)-isomer in lowering ^{3}H-DHA binding. The neuroleptics are somewhat less

potent in lowering the binding of ^{3}H-5-HT, but still display a degree of stereospecificity. The potencies of these neuroleptics in inhibiting ^{3}H-dopamine and ^{3}H-LSD binding are similar to their potencies as inhibitors of the dopamine-sensitive adenylate cyclase[1,2]. In spite of these stereospecific effects, blockade of 5-HT receptors is probably not a major source of neuroleptic clinical efficacy, because relative influences of an extensive series of these drugs on ^{3}H-LSD binding do not correlate with clinical potency[17].

Since the chemical structure of butyrophenones resembles that of the inhibitory neurotransmitter GABA[1], it was also of interest to evaluate the influence of butyrophenones on GABA uptake by synaptosome-enriched brain homogenates. In this type of tissue preparation ^{3}H-GABA is accumulated primarily by nerve terminals[16,17]. The butyrophenones examined are all capable of inhibiting ^{3}H-GABA uptake (Table 2). The most potent, fluspirilene, reduces uptake 50% at 3 μM, similar to its potency in inhibiting ^{3}H-dopamine binding and in inhibiting the dopamine-sensitive adenylate cyclase[1,2]. There is a several hundredfold variation in the relative potencies of the butyrophenones in reducing GABA uptake, and these variations correlate well with the relative clinical potencies of the drugs ($r = 0.86$, $P < 0.001$). If inhibition of GABA uptake were a common mechanism whereby therapeutic effects of all neuroleptics were elicited, then the phenothiazines and related agents should also show a similar correlation between inhibition of GABA uptake and clinical potency. We detect no correlation, however, between the influence of these agents on GABA uptake and their clinical effects. The very potent neuroleptic α-flupenthixol is no more effective in reducing GABA uptake than the weak neuroleptic promazine. Similarly, the potent neuroleptic fluphenazine has about the same potency as the moderately effective neuroleptic chloropromazine.

The most striking finding indicating that the pharmacological activity of neuroleptics related to phenothiazine cannot be attributed to influences on GABA uptake derives from experiments with stereoisomers. No difference is apparent in the potencies of α- and β-flupenthixol in competing for GABA uptake in spite of the fact that essentially all the pharmacological activity resides in the α-isomer with β-flupenthixol being essentially inactive[8]. Similarly, the cis- and trans-isomers of thiothixene have the same affinities for GABA uptake sites, though only cis-thiothixene has clinical and pharmacological activity[7].

It could be argued that the correlation between relative potencies of butyrophenones in inhibiting GABA uptake and their clinical potencies indicates that the therapeutic actions of butyrophenones may be mediated at least in part by inhibition of GABA uptake. Since uptake of GABA into nerve terminals is thought to inactivate synaptically released GABA, such an effect would potentiate the synaptic effects of GABA, which in turn could inhibit the firing of dopamine neurones Similarly inhibition of opiate receptor binding by butyrophenones but not by phenothiazines correlates well with clinical antischizophrenic activity ($r = 0.78$, $P < 0.01$ with no added Na⁺; $r = 0.61$, $P < 0.05$ with 100 mM Na⁺)[23]. There is also some correlation between antipsychotic potencies of neuroleptics and inhibition of dopamine release[6]. Before the identification of ^{3}H-haloperidol binding to dopamine receptor sites[14,22,24] these formulations might have represented plausible mechanisms for clinical effects of butyrophenones if not of phenothiazines. But since the butyrophenones are about 100–1,000 times more potent in competing for ^{3}H-haloperidol binding to dopamine receptor sites than in reducing GABA uptake, opiate binding or dopamine release and since inhibition of haloperidol binding predicts phenothiazine as well as butyrophenone activities, a more parsimonious explanation attributes clinical actions of both butyrophenones and phenothiazines to blockade of dopamine receptors[14,22,24].

The correlation between the influences of these drugs on ^{3}H-GABA uptake and clinical potencies emphasises the difficulties inherent in evaluating correlations between bio-

chemical and clinical effects of drugs. Similarly, one should be circumspect about concluding that stereospecificity of biochemical effects "proves" that one is dealing with the pharmacologically relevant site of a drug's action. Thus, if a given behavioural effect in animals is elicited more by (+)-butaclamol than by (−)-butaclamol, it should not automatically be assumed that the behaviour is dopamine mediated, since the drug effect might also involve 5-HT receptors.

Transmitter metabolism in substantia nigra after inhibition of dopaminergic neurones by butyrolactone

DOPAMINERGIC nigrostriatal neurones have recently been found to contain dopamine (DA) also in their dendrites[1]. Certain observations suggest a release of transmitter from these dendrites: depolarisation by potassium ions induces a release of ^{3}H-DA from incubated tissue slices of rat substantia nigra[2], and stimulation of the median forebrain bundle increases 3,4-dihydroxyphenylacetic acid, a major metabolic of DA[3], in the mesencephalic region containing dopaminergic cell bodies and dendrites[4], as well as in caudate–putamen, the terminal area. These similarities

between terminal and somato-dendritic areas point to a similar regulation of DA metabolism and an active role of DA in both parts of the neurone. We have studied this question in a situation where the dopaminergic neurones are inhibited. γ-Butyrolactone (GBL) applied systemically, strongly reduces unit activity of the dopaminergic neurones in zona compacta of substantia nigra[5]. Under these conditions, the changes observed in the somato–dendritic complex differed markedly from those reported for the terminal area[6-12].

In male rats (200–300 g) of a random-bred SIV (Sprague–Dawley–Ivanovas) strain, the somato–dendritic complex was analysed as a whole with biochemical techniques, while DA nerve cell bodies were studied by histochemical microfluorimetry[13]. For biochemical analyses the brains were quickly removed after decapitation, placed on dry ice and covered with carbon dioxide snow. Standardised tissue cylinders (about 1 mg) from substantia nigra were obtained as described in Fig. 1[14]. These cylinders contained the medial two thirds of zona compacta and small amounts of tissue from zona reticulata and lemniscus medialis. Their localisation corresponds to the area of highest dendritic density[1] and to the highest DA concentration in substantia nigra (F. Hefti and W. Lichtensteiger, unpublished). DA concentration was determined in individual tissue cylinders with an enzymatic–isotopic method[15]. The rate of DA synthesis was assessed by measuring accumulation of dopa after inhibition of dopa-decarboxylase with 3-hydroxybenzylhydrazine (NSD 1015, Sandev) with a newly developed enzymatic–isotopic assay[16]. In these conditions dopa accumulated linearly in substantia nigra cylinders up to 60 min (ref. 16).

Both inhibition of dopaminergic cells by GBL[6,8,9] and interruption of impulse flow by axotomy[9,10,12] have been found to lead to an increase in the concentration of dopamine in caudate–putamen. After a single injection of 750 mg kg⁻¹ of GBL. DA concentration was greatly increased between 15 and 150 min (ref. 8). We could confirm
Fig. 1 Localisation of standardised tissue cylinders in substantia nigra. From frozen brain, a 1-mm thick frontal slice was sectioned extending anteroposteriorly from level A 1400 to level A 2400 according to the atlas of Koenig and Klippel[20]. A cylinder of 1-mm diameter was punched out on each side. The figure shows the histological control of such a slice fixed after punching (Toluidine blue staining). c, Zona compacta; r, zona reticulata of substantia nigra; lm, lemniscus medialis; cc, crus cerebri.
Fig. 2 Effect of γ-butyrolactone (GBL) on DA concentration (hatched bars) and dopa accumulated in substantia nigra 30 min after injection of the dopa-decarboxylase inhibitor NSD 1015 (100 mg kg^{-1} intraperitoneally; solid bars). Open bars represent saline injected controls. (Mean $\pm$s.e.m.; $n = 9$–10; *$P<0.025$; **$P < 0.005$). Concentration of DA and dopa were based on protein content of tissue cylinders[21]. Mean $\pm$s.e.m. of DA control levels was 15.0 ± 1.1 ng per mg protein, mean of dopa accumulated in 30 min was 8.3 ± 0.8 ng per mg protein in control animals.

this effect in rats (at 60 min) and observed a comparable change in mice (at 10 and 90 min; unpublished). In contrast to this the DA concentration in substantia nigra was not raised after 35 and 60 min; there was even a reduction after 15 min (Fig. 2). The quantitative histochemical investigation of DA perikarya in zona compacta of substantia nigra revealed no changes in fluorescence intensity in male rats 60 min after GBL, while intensity tended to decrease in male mice at 10 min and 90 min after drug administration (Table 1). This is again at variance with the response of DA terminals, where GBL elicits a marked rise in fluorescence intensity[7,17].

Also with regard to DA synthesis, our observations on the somato–dendritic area (Fig. 2) contrast with the findings in the terminal region[10,11]. In substantia nigra, dopa accumulation remained about 40% below control level at

35 and 60 min, whereas the amount of dopa accumulated in caudate-putamen has been shown to be more than doubled 35 min after GBL and to be again at control levels after 90 min[10].

Since the decarboxylase inhibitor NSD1015 was reported to slightly inhibit monoamine oxidase[18], it could be argued that the absence of an increase in DA synthesis rate in substantia nigra might be related to effects on intraneuronal feedback mechanisms on tyrosine hydroxylase. The effects of GBL on dopa accumulation in caudate-putamen were studied with another inhibitor of dopa-decarboxylase, N^1-(DL-seryl)-N^2-(2,3,4-trihydroxybenzyl)-hydrazine (Ro 4-4602) (ref. 10). In caudate-putamen, however, an increased accumulation of dopa was found after inhibition of impulse flow by axotomy also with NSD1015 (ref. 11). Moreover, Walters and Roth[19] have shown that prior application of an inhibitor of monoamine oxidase does not prevent the increase in dopa accumulation in caudate-putamen after Ro 4-4602 and GBL, only the magnitude of the effect was slightly reduced. Inhibition of monoamine oxidase for 30 min did not deruce dopa accumulation after Ro 4-4602 alone. Therefore, it seems that the discrepancies between substantia nigra and caudate-putamen are not related to the type of decarboxylase inhibitor used, but rather reflect a true difference between the two regions.

Our findings indicate that somatodendritic and terminal areas of dopaminergic neurones differ with regard to the regulation of monoamine metabolism at least in some functional states. The relative importance of biochemical changes in dendrites and perikarya is as yet difficult to assess. A rise in dendritic DA after GBL may have been obscured by a fall in DA concentration of perikarya, or else, it may have been too small to be detected against the background of perikaryal DA. Our microfluorimetric data speak against the first possibility. Moreover, the contribution of dendrites to nigral DA seems to be considerable, as DA concentration in zona reticulata, which contains mainly dendrites, is relatively high (4.2 ± 0.7 ng per mg protein; mean$\pm$s.e.m.; $n=10$) as compared to zona compacta containing a mixture of perikarya and dendrites (14.9 ± 1.5 ng per mg protein; $n=10$). It follows from these considerations that the dopaminergic dendrites themselves probably responded to GBL in a way different from the reaction of terminals.

Table 1 Fluorescence intensity of dopamine-containing nerve cells in zona compacta of substantia nigra*

Treatment	Mean relative fluorescence intensity†	Mean $\pm$ s.d. of logarithmically transformed intensity distribution (natural log)	Cell count (No. of animals)
Male rats			
Saline, 60 min	60.58	4.044 ± 0.3602	779 (5)
GBL 750 mg kg^{-1}, 60 min	62.44	4.063 ± 0.3842	762 (5)
Male mice			
Saline, 10 min	51.32	3.861 ± 0.4150	749 (5)
Saline, 40 min	52.47	3.866 ± 0.4548	803 (5)
GBL 375 mg kg^{-1}, 10 min	48.42	$3.790\pm0.4515\ddagger$	782 (5)
GBL 375 mg kg^{-1}, 90 min	48.11	$3.755\pm0.5382\ddagger$	781 (5)

*The nigral DA neurone group was investigated in 8 frontal 7-μm sections (distance between sections = 35 μm). Twenty neighbouring cells were measured in each section, starting at the dorsolateral corner of zona compacta (for further details, compare refs 13 and 22). The experiments on mice were performed in the course of a study on morphine action; controls are taken from that study[22].
†Mean relative intensity in per cent of noradrenaline standard. For statistical analysis, the values of individual cells were logarithmically transformed. Mean values were compared according to Scheffé's method of linear contrasts[13].
‡Different from both saline controls for $P < 0.05$.

Technique for studying synaptic connections of single motoneurones in man

DURING normal voluntary muscle contractions, the pattern of discharge of a single motoneurone is determined by the summed effects of an enormous variety of different types of synaptic input. In principle, the effect of any one of these inputs could be determined by constructing a histogram of the time of occurrence of motoneurone spikes after repeated presentation of a suitably controlled stimulus[1,2]. This procedure extracts from the naturally occurring spike train only those changes in firing time locked to the stimulus. The synaptic effect of a given input is thus revealed in terms of the specific contribution it makes to the total firing pattern of the cell. Such studies are

Fig. 1 *a*, Post-stimulus time histogram of the occurrence of the action potential of a single motor unit in the first dorsal interosseous muscle after a sharp tap to the tip of the nail of the index finger. Stimuli delivered at $3 s^{-1}$ while the subject maintained an isometric contraction such that the unit fired steadily at about 8 p.p.s. 4,096 sweeps. Bin width 1 28 ms. Stimulus given at time zero. *b*, Twitch response of the same motor unit recorded by averaging the force of abduction of the index finger exerted at the second proximal interphalangeal joint triggering the averager from the motor unit action potential while the subject maintained a contraction such that the unit fired at < 3 p p s For details of method see refs 3 and 4. 64 sweeps. Threshold of recruitment 160 g.

most conveniently carried out in man where the cooperation of the subject is invaluable. This report describes an example of this approach in the study of the synaptic effects of a simple cutaneous input. In more general terms, the experimental situation described enables, for the first time, the synaptic connections of single motoneurones to be examined in man, studies previously only attempted in anaesthetised or decerebrate animals.

Figure 1*a* shows the changes in probability of firing of a single motor unit in a hand muscle after a sharp mechanical tap to the tip of a fingernail. At 39 ms after the tap there is an increase in probability of occurrence of the motor unit action potential which reaches a maximum 7 ms later. This period of excitation is immediately followed by a period of inhibition during which the probability of motor unit firing reaches a minimum at 58 ms. This itself is terminated by another more pronounced and prolonged period of excitation reaching a

maximum at 76 ms. This is followed by some rather slow fluctuations superimposed on a prolonged period of reduced probability which eventually returns to control about 300 ms after the initial stimulus[5]. The timing of these responses suggests that the earliest excitation and inhibition involve spinal pathways and that the later more pronounced excitation involves supraspinal pathways[6,7].

The possibility that these responses might be due to vibration transmitted to muscle receptors has been tested by anaesthetising the index finger. The responses can be abolished either by a 2% Lignocaine or by an ischaemic block of the digital nerves. Moreover, weak electrical stimulation of the digital nerves at two times threshold for perception gives essentially the same result as tapping the nail.

The scale of the response to such a modest and limited stimulus, illustrates the most powerful influence that a cutaneous afferent volley can exert on the discharge of a motoneurone. During the initial inhibitory phase, the unit is almost completely silenced. Immediately after this, the mean firing rate is more than doubled. It is clear that the results of experiments in which the response of the motor system is studied after sudden external disturbance must be interpreted with caution if any sudden displacements of the skin are involved[8].

The results of the present type of experiment gain additional significance because the reflex connections of a motoneurone can be related to its recruitment threshold during voluntary muscle contraction and to the mechanical properties of the muscle fibres it innervates (Fig. 1*b*). It will now be possible, in man, to test the applicability of the unexpected subtleties revealed by intracellular recording in the synaptic connections of cat hind limb motor units with different mechanical properties[9,10].

Voltage-dependent action of tetrodotoxin in mammalian cardiac muscle

TETRODOTOXIN (TTX) in many excitable membranes selectively blocks the transient change in sodium conductance which underlies the rising phase of the action potential. Electrophysiological and binding studies from nerve and skeletal muscle[1–5] indicate that a one-to-one binding reaction between toxin and Na channels with a dissociation constant of about 5×10^{-9} M can adequately describe the kinetic and steady-state actions of TTX on the Na conductance. Cardiac muscle is unusual in that it shows a marked insensitivity to TTX. A substantial reduction in the rate of rise of action potentials in ventricular trabeculae and Purkinje fibres does not occur until a TTX concentration of about 10^{-6} M is reached[6–8]. We report here the results of a systematic study of the effects of TTX on mammalian cardiac muscle. The experiments were designed to determine whether the reported difference in sensitivity to TTX is an indication of basic differences in the TTX receptor of cardiac muscle as compared to nerve and skeletal muscle. Unlike any TTX effects reported in other tissues[6], our results show a voltage dependence of TTX block. This suggests possible differences in the structure of the TTX binding site or of the Na channel itself.

Intracellular membrane action potentials were recorded from guinea pig papillary muscles by conventional microelectrode techniques, and the maximal upstroke velocities ($\dot{V}_{max}$) of the action potentials were differentiated electronically. The papillary muscles were mounted in a single sucrose gap arrangement as described previously[9]. The sucrose gap permitted uniform displacement of the membrane potential in the short (< 0.8 mm) muscle end where action potentials were recorded. The muscles were stimulated with brief current pulses (5 ms; 0.3 Hz), and

occasionally long lasting depolarising or hyperpolarising constant currents were applied. Our experiments showed that $\dot{V}_{max}$ was linearly related to the extracellular Na concentration (correlation coefficient, $r = 0.99$), indicating that the corresponding membrane current is carried by Na ions as in other excitable tissues. The blocking action of TTX on $\dot{V}_{max}$ reached a steady state in about 5 min, and no further effect of the toxin was seen after continuous exposure for up to 2 h. For concentration–response curves, $\dot{V}_{max}$ measurements were typically made after 15 min equilibration in solutions containing toxin and can be considered as steady state. Continuous microelectrode impalements in a single cell were routinely maintained throughout an experiment allowing a direct comparison of the effects of several toxin concentrations on a given cell at two membrane potentials. Membrane resting potential, V_r, was either changed by increasing the potassium concentration in normal Tyrode's solution (5.4 K⁺-Tyrode's) to 10.8 mM (10.8 K⁺-Tyrode's) or by passing constant currents across the sucrose gap.

The concentration dependence of TTX inhibition of $\dot{V}_{max}$ is shown in Fig. 1. The curves were fitted by assuming a first-order reaction between toxin and receptor. The half-maximal inhibition of $\dot{V}_{max}$ in 5.4 K⁺-Tyrode's occurs at 1.4×10^{-5} M TTX. Doubling the potassium concentration of the Tyrode's solution profoundly affects the sensitivity of the muscle to TTX. Only 1.2×10^{-6} M TTX is required for half-maximal inhibition of $\dot{V}_{max}$ in 10.8 K⁺-Tyrode's. The high potassium solution depolarised the fibres from -89 ± 3 mV to -71 ± 3 mV ($\pm$s.e.). The increase in apparent affinity to TTX is a result of this depolarisation and not of the increased K⁺ concentration *per se*, since a depolarisation of similar magnitude produced by passing a constant current through the fibre had a similar effect on the TTX sensitivity.

$\dot{V}_{max}$ is an indirect and nonlinear measure of the maximal sodium conductance g_{Na} (refs 3 and 10) which is actually the parameter directly affected by TTX binding[1,3,6]. We thought it possible that the depolarisation induced decrease in the control value of $\dot{V}_{max}$ (Figs 1 and 2) might change the relationship between $\dot{V}_{max}$ and g_{Na} (ref 10), which in turn could alter the apparent sensitivity to TTX. Therefore, we carried out experiments with 5.4 K⁺-Tyrode's solution in which 50% of the Na⁺ had been replaced with choline⁺. In these conditions $\dot{V}_{max}$ is reduced by half—that is, even more than in 10.8 K⁺-Tyrode's. There was a small, non-significant ($P > 0.1$) difference in the concentration–response curves in normal and low Na⁺-Tyrode's which could not explain the depolarisation-induced
Fig. 1 *a*, Concentration–response curves showing the effects of TTX (log scale) on maximum upstroke velocity ($\dot{V}_{max}$; mean $\pm$ s.e.) of the action potential in 5.4 ($\times$) and 10.8 ($\bullet$) mM K⁺-Tyrode's. The inset is a schematic drawing of resting potential (V_r) and action potential (upper trace); the latter was differentiated electronically (lower trace) and the maximal upstroke velocity ($\dot{V}_{max}$) was measured. *b*, Normalised mean values of *a*. Solid lines are concentration–response curves calculated from the equation

$$\dot{V}_{max\ TTX} = \dot{V}_{max\ control}\,(1 - [1/(1 + \{K_m/[TTX]\})])$$

$\dot{V}_{max\ control}$ and K_m were 167 V s⁻¹ and 1.4×10^{-5} mol l⁻¹ in 5.4 K⁺-Tyrode's, and 109 V s⁻¹ and 1.2×10^{-6} mol l⁻¹ in 10.8 K⁺-Tyrode's. Numbers of determinations per mean value given in parentheses in *a*.

increase in sensitivity to TTX. We do not yet know whether the measurements of V_{max} reflect directly the true binding behaviour of TTX to the Na channels. Studies on skeletal muscle, however, show that measurements of V_{max} give values for the apparent dissociation constant of TTX which agree within factors of 2–6 with those obtained from binding studies[4,5,11].

The concentration–response curves in Fig. 2 were taken from a single papillary muscle which was treated with various TTX concentrations in 10.8 and 5.4 K$^+$-Tyrode's. Initially the preparation was superfused with 10.8 K$^+$-Tyrode's and the concentration of TTX was increased until V_{max} was completely
Fig. 2 Concentration–response curves of TTX on V_{max} in 10.8 (●) and 5.4 (×) mM K$^+$-Tyrode's. Data were collected from one papillary muscle during a single microelectrode impalement. *a*, Bars on the left give control values of V_{max} before application of TTX. Initially, the preparation was bathed in 10.8 K$^+$-Tyrode's and the TTX concentration (log scale) increased until V_{max} fell to zero; 5.4 K$^+$-Tyrode's containing 10^{-4} mol l^{-1} TTX was then applied and V_{max} returned to 45% of its normal value and fell again to zero upon further increase in the TTX concentration. *b*, Changes in the resting potential (V_r) caused by the variation in potassium concentration.

abolished, even after increasing the stimulus strength. When the solution was changed to 5.4 K$^+$-Tyrode's containing the same amount of toxin that had caused a complete block of V_{max} in 10.8 K$^+$-Tyrode's, a rapid recovery of V_{max} to about 50% of its control value occurred, while V_r hyperpolarised by 16 mV. When the TTX concentration was increased further, the fibre again showed the lower sensitivity to toxin expected at this V_r. One possible explanation of this effect is that the Na channels inactivated during depolarisation are protected from TTX binding, but become sensitive to TTX again on hyperpolarisation when inactivation is removed.

We have tested this possibility by incubating non-stimulated muscles for 10 min with TTX (10^{-4} M) at −85 mV where all Na channels are available and at −50 mV (20 K$^+$-Tyrode's) where they are fully inactivated[9,13]. When the muscles were rapidly hyperpolarised by passing a constant current and stimulated from a V_r of about −90 mV, the degree of inhibition of V_{max} was slightly larger following the period of inactivation. This suggests that the depolarisation induced inactivation of the Na channels did not protect them from the TTX action. Therefore, we explain the result in Fig. 2 in terms of a release

of TTX during hyperpolarisation to −87 mV from Na channels which were blocked by the toxin at −71 mV. In other words, the hyperpolarisation partially removed the TTX block attained at the lower V_r. This argues strongly for voltage dependence of TTX binding.

Our results indicate at least two major differences between the action of TTX in cardiac muscle and in nerve or skeletal muscle. First, V_{max} of action potentials of cardiac muscle is three to four orders of magnitude less sensitive to the toxin. Second, the sensitivity of cardiac fibres to TTX is voltage dependent, a depolarisation of approximately 18 mV from the normal V_r being sufficient to change the apparent affinity by a factor of 10. The voltage-dependent effects of TTX on cardiac muscle indicate to us a basic difference in the chemistry or configuration of the TTX receptor, or of the Na channel[13]. Possible differences in the structure of the Na channel in cardiac muscle as compared with other excitable tissues are relevant to the mechanism of action of antiarrythmic drugs, which primarily affect the Na conductance system.

Localisation of gonadotropin-releasing and thyrotropin-releasing hormones in human brain by radioimmunoassay

Gonadotropin-releasing hormone (GnRH) and thyrotropin-releasing hormone (TRH) are two hypothalamic oligopeptides which regulate the secretion of gonadotropins and of thyroid-stimulating hormone (TSH), respectively, from the anterior pituitary[1,2]. It is generally accepted that these neurohormones are produced by nerve cells, transmitted along axons and stored in nerve endings; when released, they are transferred by way of the hypothalamo–hypophyseal portal system to the anterior pituitary[3]. Human brains of adults have been shown to contain GnRH and TRH activity[4] but quantitative measurements of these hormones are available for brains of aborted foetuses only[5]. This report deals with the distribution of GnRH and TRH in the adult human brain, their possible sites of formation, routes of migration and sites of storage in the pituitary stalk.

The hypothalami and other brain regions were removed during routine autopsies carried out at the Institute of Forensic Medicine, Tel Aviv. The tissues were obtained from three 22–40-yr-old females and twelve 41–95-yr-old males, most of them killed in road accidents. The bodies were kept for 6–48 h at 4 °C until autopsy. The pituitary stalk and gland were dissected
Fig. 1 Outline of the dissection of the human hypothalamus and pituitary stalk. Hypothalamus was dissected in the coronal planes to six strips (broken lines, A–F) or into 25 blocks (solid lines). The pituitary stalk was sectioned into eight portions (including the infundibular stem). Insert: mid-sagittal section of the human brain. AC, Anterior commissure; CF, column of fornix; DM, dorsomedial nucleus; HS, hypothalamic sulcus; IN, infundibular nucleus; INF, infundibulum of neurohypophysis; IP, infundibular process of neurohypophysis; IS, infundibular stem of neurohypophysis; MB, mammillary body; MI, massa intermedia; OC, optic chiasma; ON, oculomotor nerve; OPN, optic nerve; PC, posterior commissure; PD, pars distalis of adenohypophysis; PEC, peduncle of cerebrum; PI, pineal body; PO, preoptic nucleus; PON, pons; PN, posterior nucleus; PT, pars tuberalis of adenohypophysis; PV, paraventricular nucleus; SO, supraoptic nucleus; SM, stria medullaris; VM, ventromedial nucleus.

from the hypothalamus. Each brain was cut midsagittally and each half of the hypothalamus was sectioned in the coronal plane to six strips (Fig. 1 A–F). In four brains one half of the hypothalamus was sectioned into 25 blocks (Fig. 1); the pituitary stalk was sectioned into seven horizontal slices and the infundibular stem, infundibular process (posterior pituitary) and the pars distalis (adenohypophysis) were also collected. Each of the sectioned pieces was weighed, extracted and analysed for GnRH and TRH by radioimmunoassay as described previously[6,7].

In a preliminary study we have found that in the rat the hypothalamic content of GnRH and TRH did not change up

to 48 h after death. Male rats (12 per group) were killed with ether. In one group, the hypothalami were removed and extracted immediately, and the other group kept for 48 h at 4 °C before removal and extraction of hypothalami. Hypothalamic content of GnRH was 4.4±0.3 ng at death compared with 4.0±0.3 ng 48 h later, and of TRH was 7.4±0.1 compared with 7.2±0.3 ng.

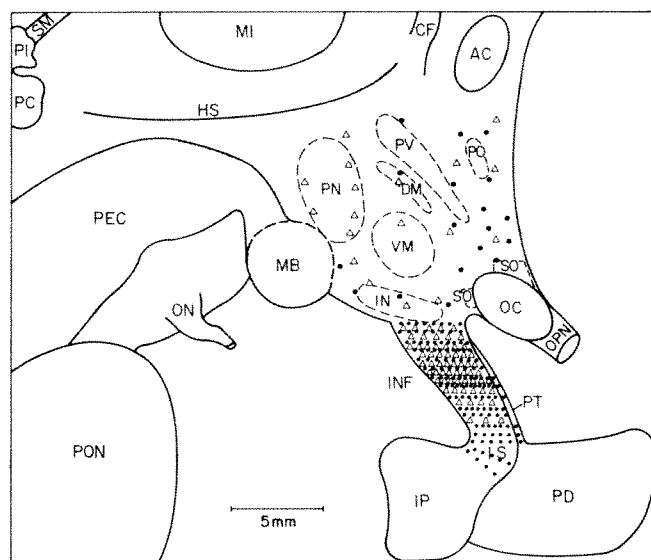
The content of GnRH and of TRH in the human hypothalamus were initially estimated by assaying the dissected strips (Fig. 1 A–F). The results are summarised in Table 1. The concentration of GnRH was the highest in the rostral strip


Fig. 2 Localisation of GnRH (●) and of TRH (△) in the human hypothalamus and pituitary stalk. The outline of hypothalamic nuclei in the sagittal plane are shown in broken lines. Each dot or triangle represents a concentration of 70–110 pg/mg tissue of the corresponding neurohormone. For abbreviations, see Fig. 1.

(A), which comprises the preoptic area, and declined progressively towards the caudal strip (F), which contained negligible amounts of GnRH. A different pattern of distribution was observed for TRH (Table 1): the highest concentration was found in strip C which consists of the posterior nucleus and the premammillary area. Radioimmunoassay of extracts derived from hypothalamic tissue blocks (Fig. 1), enabled us to follow more precisely the localisation of GnRH and TRH. GnRH was localised mainly in the preoptic area (Fig. 2), between the

Table 1 GnRH and TRH concentrations in the human brain

Sample	Weight (mg)	GnRH (pg per mg tissue)	TRH (pg per mg tissue)	Total GnRH (ng)	Total TRH (ng)
Hypothalamus					
Strip A	72 ± 14	130 ± 59	54 ± 10	9.36	3.88
B	98 ± 16	62 ± 24	73 ± 8	6.07	7.15

*Including infundibular stem.
Each tissue sample was weighed, extracted and analysed by radioimmunoassay for GnRH and TRH content. Mean ± s.e.m. for 10–15 samples, are shown. Total amount of the hormones in hypothalamic strips (A–F) represents the content of half a hypothalamus, dissected in the midsagittal plane.
Fig. 3 Scheme of the neurovascular pathway of GnRH and TRH in the human brain. ●, Cell bodies of TRH-producing neurones in the posterior nucleus (PN). TRH is transferred by axons (solid lines) to the capillary loops in the pituitary stalk and reach the pars distalis (PD) of the adenohypophysis by way of the long portal vessels (LPV). ●, Cell bodies of GnRH-producing neurones in the preoptic area of the hypothalamus. Their axons (broken lines) terminate on the capillary loops of the superior hypophyseal artery (SHA) and the inferior hypophyseal artery (IHA), and reach the adenohypophysis by way of both the long (LPV) and short (SPV) portal vessels. The location of the portal vessels was drawn according to Daniel and Prichard[8]. For abbreviations, see Fig. 1.

supraoptic and the preoptic nuclei (340 pg per mg tissue); high concentration was also found in an area located anterior to the mammillary body in the basal hypothalamic area (186 pg per mg tissue). The highest concentration of TRH was observed in the posterior nucleus (158 pg per mg tissue) and in the region connecting this nucleus with the pituitary stalk. Exceedingly high concentrations of both neurohormones were present in the pituitary stalk (1,430 pg per mg tissue and 855 pg per mg tissue for GnRH and TRH, respectively; Table 1), with a difference in distribution (Fig. 2): GnRH was evenly distributed all along the pituitary stalk, whereas TRH was localised in the upper two-thirds (except for one case). The total content of GnRH in the hypothalamus was 40.5 ng and in the pituitary stalk 58.6 ng. Hypothalamic content of TRH was 61.7 ng and of the pituitary stalk 35 ng. No significant amounts of the hormones were detected in the different regions of the pituitary gland. Low concentrations of TRH were found in some extra-hypothalamic regions of the brain (Table 1). No apparent differences in the distribution or content of the two neurohormones were observed in relation to age or sex.

Axons descending from the hypothalamus have been shown to constitute the major component of the pituitary stalk[8]. Therefore, the extremely high concentrations of GnRH and TRH in the pituitary stalk (Fig. 2), may reflect the presence of pools of these hormones stored in axons and nerve terminals. Localisation of TRH and GnRH in specific hypothalamic regions may represent sites of synthesis of the hormones in neuronal cell bodies of these areas. In the rat, relatively high concentrations of GnRH have been found in the preoptic area and in the arcuate–median eminence region[9]. The median eminence of the rat, however, is anatomically homologous to the proximal portion of the human pituitary stalk[8]; therefore, the distributions of GnRH in human (that is, high concentrations in the preoptic area and the pituitary stalk) and rat hypothalamus, are similar.

An additional pathway—that is, by way of the cerebrospinal fluid—has been suggested[10] for the transfer of the neurohormones from their site of synthesis to their site of release. The high concentrations of GnRH in the lowest portion of the infundibular stem (Fig. 2), which is remote from the infundibular recess of the third ventricle, favours the direct neural route.

The absence of TRH in the lower third of the pituitary stalk implies that this neurohormone reaches the anterior pituitary by way of the long portal vessels (Fig. 3), whereas GnRH, which is evenly distributed along the whole pituitary stalk and infundibular stem, is transported by way of both the long and short portal vessels.

We thank Dr B. Bloch, Institute of Forensic Medicine, for assistance. E. O. is a visiting scientist from the Department of Pathology, Hadassah University Hospital, Jerusalem.

Evidence for an extranucleolar mechanism of actinomycin D action

SINCE the original observation of Perry[1] that a low concentration of actinomycin D (0.04 µg ml⁻¹) selectively inhibits ribosomal RNA (rRNA) synthesis *in vivo*, this concentration of drug has been used by numerous investigators to selectively inhibit the synthesis of rRNA in cells in culture. Since nucleolar ribosomal DNA contains a high amount of deoxyguanosine and deoxycytosine bases[2] and actinomycin D selectively binds to deoxyguanosine[3], it has been thought that actinomycin D preferentially binds to nucleolar DNA to inhibit the transcription of 45S ribosomal RNA precursor.

α-Amanitin, the peptide toxin from *Amanita phalloides*, also has inhibitory effects on the synthesis of rRNA[4–6] and is known to produce nucleolar fragmentation[7–10]. Since α-amanitin is a potent inhibitor of nucleoplasmic RNA polymerase II (refs 11–13) and protein synthesis is an integral component of rRNA synthesis[14–17], it is conceivable that α-amanitin and actinomycin D have comparable sites of action in inhibiting the transcription of mRNA(s) coding for the essential protein(s) required for the initiation of rRNA transcription *in vivo*. Although these observations with α-amanitin have suggested the possibility of an extra-nucleolar control of rRNA synthesis, a specific role of mRNA in this process remains to be demonstrated. In this report, evidence is presented for an extranucleolar mechanism of actinomycin D action suggesting that rRNA transcription in nucleoli is controlled by mRNA synthesis in the nucleoplasm.

Studies in this report were designed to ask two questions: (1) Is α-amanitin resistant transcription in isolated nuclei (RNA polymerase I + III) and purified nucleoli (RNA polymerase I) inhibited by the low concentrations of actinomycin D known to be effective *in vivo*; and/or, (2)
Fig. 1 Effect of actinomycin D on transcription in isolated nuclei and nucleoli. RNA polymerase assays, in the presence of varying concentrations of actinomycin D were performed as described below. Liver nuclei were isolated from adult male rats (300 g) by the method of Blobel and Potter[18] with 1 mM phenylmethylsulphonylfluoride (PMSF) in all buffers according to Lindell[19]. Nucleoli were isolated from freshly prepared nuclei by resuspension of the nuclear pellet obtained above in 0.34 M sucrose. The nuclear suspension was then sonicated and fractionated according to Roeder and Rutter[20]. The yield of nucleoli was 30–40% as calculated from the assay of RNA polymerase I activity in protein solubilised from starting nuclei and nucleolar product[21]. Routine preparations of nucleoli contain 0.5% RNA polymerase II by assay of RNA polymerase activity without exogenous DNA, plus and minus α-amanitin. RNA polymerase assays in rat liver nuclei and nucleoli were performed as described by Zerwekh *et al.*[22] using a single concentration of $(NH_4)_2SO_4$ (0.05 M). Actinomycin D (Merck) was added in 10-μl aliquots to 50-μl nuclear samples to give final concentrations (in 125 μl) ranging from 0.001 to 100 μg ml^{-1} (6.6 × 10^{-11}–6.6 × 10^{-5} M). Nuclei and nucleoli were preincubated with actinomycin D at room temperature for 10 min before initiation of the assays by addition of substrates and 5-^{3}H-UTP (New England Nuclear, 25 Ci mmol^{-1}). Individual nuclear assays (5 in the absence and 5 in the presence of α-amanitin, 0.1 μg per assay) were incubated for 5 min at 30 °C. Incorporation of ^{3}H-UMP was linear within this time period. Nucleolar assays were performed in the presence of α-amanitin to inhibit any possible residual RNA polymerase II activity. All incubations were terminated by pipetting 100-μl aliquots of each assay on to Whatman DE-81 filter disks and immediately placing them in 5% Na_2HPO_4. The filters were then washed, and counted as described by Lindell *et al.*[11]. Nucleoplasmic form II RNA polymerase activity was quantitated by subtracting the c.p.m. incorporated in the presence of α-amanitin from those assays performed in the absence of α-amanitin. Nuclear forms I and III RNA polymerase activities were quantitated by subtracting the c.p.m. obtained from control incubated samples containing 80 μg ml^{-1} actinomycin D plus α-amanitin (0.1 μg per assay) from the c.p.m. incorporated in the presence of α-amanitin alone. There is no linear incorporation of ^{3}H-UMP into RNA in this control. Activities of RNA polymerases are expressed as pmol UMP incorporated per 5 min per mg DNA. DNA determinations were performed on identical 50-μl aliquots of the same nuclear-nucleolar samples used for RNA polymerase assay by the method of Burton[23] using calf thymus DNA (Sigma, Type II) as a standard. Each point represents the average of five individual determinations ±s.e.m. Where error bars are not evident, they lie within the symbol. Control activities were: α-amanitin sensitive nucleoplasmic (form II RNA polymerase), 198; nuclear α-amanitin insensitive nucleoplasmic (forms I and III RNA polymerases), 114; and isolated nucleoli, 241 pmol UMP incorporated per 5 min per mg DNA, respectively. ●, Nucleoplasmic polymerase II; ○, nuclear RNA polymerases I and III (α-amanitin insensitive 0.1 μg per assay); and □, isolated nucleolar (RNA polymerase I) transcription. The arrow indicates 0.04 μg ml^{-1} actinomycin D.

Is there any nucleoplasmic component of *in vitro* transcription in nuclei which is inhibited by actinomycin D? Briefly, nuclei and nucleoli were isolated from adult rat livers and resuspended in a sucrose buffer. Actinomycin D was preincubated with these organelles before the addition of 5-^{3}H-UTP and substrates. Reactions were terminated by pipetting samples on to filter paper disks, washed, and counted as described in the legend to Fig. 1.

The effect of actinomycin D on the various RNA polymerase activities in isolated rat liver nuclei and purified nucleoli is shown in Fig. 1. Since actinomycin D inhibits rRNA transcription *in vivo* in the concentration range 0.001–0.1 μg ml^{-1} (ref. 24), it was surprising to observe that transcription in isolated nucleoli was inhibited at concentrations almost 100 times greater. Transcription in isolated nuclei in the presence of α-amanitin shows near identical inhibition to that observed in nucleoli except that the curve is biphasic. This additional activity between 1 and 10 μg ml^{-1} actinomycin D was inhibited by higher concentrations of α-amanitin (400 μg ml^{-1})[25] and, therefore, confirmed to be RNA polymerase III (data not included). An additional experiment was performed to rule out the possibility that actinomycin D was not preincubated with isolated nucleoli for an adequate amount of time for sufficient inhibition to occur. Figure 2 presents this experiment in which isolated nucleoli were incubated at 30 °C in the presence of 0.04 and 0.1 μg ml^{-1} actinomycin D relative to a control nucleolar sample incubated in the absence of actinomycin D. Samples of nucleoli were withdrawn at 15, 30, 45 and 60 min to test for the ability of the endogenous
Fig. 2 Effect of actinomycin D preincubation with purified nucleoli on the activity of endogenous nucleolar RNA polymerase I. Actinomycin D at 0.04 and 0.1 μg ml^{-1} were preincubated with identical nucleolar samples at 30 °C for varying times up to 60 min. Aliquots (50 μl) were removed at the times indicated and pipetted into ^{3}H-UTP and substrates for assay of endogenous nucleolar polymerase activity as described in the legend of Fig. 1. Results obtained with actinomycin D are plotted along with an identical nucleolar sample which contained no actinomycin D. ○, Control; △, 0.04 μg ml^{-1} actinomycin D; and □, 0.1 μg ml^{-1} actinomycin D. RNA polymerase activity is expressed as pmol UMP incorporated per 10 min per mg DNA.

RNA polymerase I to transcribe nucleolar DNA. This experiment demonstrated that actinomycin D is still ineffective in inhibiting transcription in isolated nucleoli after pre-incubation of these organelles up to 1 h. The loss of activity with time may be related to the spontaneous loss of RNA polymerase I activity as previously described by Lindell[19] or to thermal inactivation of the enzyme.

Nucleoplasmic transcription by RNA polymerase II is biphasically inhibited by actinomycin D. Twenty per cent of the total nucleoplasmic RNA polymerase activity is inhibited by actinomycin D in the concentration range 0.001–0.1 $\mu g\ ml^{-1}$, whereas the remaining 80% is inhibited between 0.1 and 100 $\mu g\ ml^{-1}$. The first phase of nucleoplasmic polymerase transcription is inhibited at a concentration of actinomycin D 700 times lower than that required for the inhibition of the remaining nucleoplasmic activity.
Fig. 3 Correlation of the inhibition of nucleoplasmic transcription *in vitro* with the inhibition of 45S RNA synthesis in mouse L cells *in vivo* (data of Perry and Kelley[24]) by actinomycin between 0.001 and 0.08 $\mu g\ ml^{-1}$. The first phase of nucleoplasmic transcription (Fig. 1) was relativised to 100% and compared with the data of Perry and Kelley[24] (their Figs 4 and 7, 100 and 60 min preincubation of mouse L cells with actinomycin D, respectively). ●, Nucleoplasmic transcription (this study); □, Perry and Kelley, 60-min preincubation (their Fig. 7); and △, 100-min preincubation (their Fig. 4).

Although actinomycin D inhibition of *in vitro* transcription seems to be reversed with regard to nucleolar and nucleoplasmic RNA synthesis, there is at least one consistency with another observation of actinomycin D inhibition in cells in culture relative to this work. It is clear from the work of Perry and Kelley[26] that 4S and 5S RNA synthesis which is transcribed by RNA polymerase III (ref. 25), is 50–100-fold less sensitive to inhibition than 45S RNA transcription in mouse L cells. This is also apparent in this *in vitro* work but the concentration range of actinomycin D which affects 45S RNA transcription *in vivo* only affects nucleoplasmic RNA synthesis (presumptive mRNA). The relationship of this actinomycin D inhibition of nucleoplasmic transcription in rat liver nuclei *in vitro* to the inhibition of 45S RNA synthesis in mouse L cells is shown in Fig. 3. It can be seen that an excellent correlation exists between these two heterologous observations.

Perhaps the most severe criticism of this work is that transcription in these organelles is not sufficiently sustained to allow any reasonable conclusions from a study such as this. Zylber and Penman[27] have concluded that transcription in Hela cell nuclei is merely completion of synthesis which had already initiated *in vivo*. In fact, transcription in isolated rat liver nuclei assayed in these conditions (polymerase II and polymerases I + III) is only linear for about 5 min. Transcription in isolated nucleoli assayed in identical conditions is, however, linear for 30–45 min. In spite of the lack of sustained transcription in isolated nuclei, there is a reasonable correlation with the inhibition of nucleolar transcription and the activity of α-amanitin-insensitive RNA polymerase activity in nuclei (Fig. 1).

The information presented in this manuscript lends further support to a possible extranucleolar control of rRNA transcription *in vivo*. Since actinomycin D only inhibits transcription by RNA polymerase II *in vitro* in the identical concentrations which inhibit 45S RNA transcription *in vivo*, it is likely that this extranucleolar control resides at the level of mRNA transcription. In fact, other investigators have observed an inhibition of nucleoplasmic RNA transcription by low concentrations of actinomycin D in eukaryotic cells in culture[24,27,29]. The amount of nucleoplasmic RNA inhibited ranged from 5 to 50% depending on the cell type and the concentration of actinomycin D used.

If rRNA transcription is controlled by nucleoplasmic RNA polymerase II transcription (mRNA) as suggested by these data, then a rational hypothesis can be formulated with regard to the early observations of Fiume and Laschi[7] regarding nucleolar fragmentation induced by α-amanitin. While inhibitory effects of α-amantin on rRNA synthesis have been observed[4–6], others have seen no effect of this compound in specific cell types[10,30]. It is, however, clear from these studies that α-amanitin probably does not easily penetrate the cell membrane because nucleolar fragmentation is not evident until 6–8 h after addition of α-amanitin (5 $\mu g\ ml^{-1}$) to CHO cells and effects on rRNA synthesis are not observed until 24 h (ref. 10). For α-amanitin to be an effective inhibitor of rRNA transcription by the proposed pathway, all RNA polymerase II molecules must be inhibited to be assured that the expression of any specific genome is terminated. Actinomycin D, on the other hand, probably acts at a specific DNA site(s) which has a very high affinity for binding and, hence, a selective inhibitory action. These data would predict that that site is nucleoplasmic rather than nucleolar.

Possible pathway for prebiotic uracil synthesis by photodehydrogenation

THE synthesis of purines in potentially prebiotic conditions has been demonstrated[1,2]. Adenine and guanine have been synthesised directly from aqueous cyanide solutions and a mechanism for the concentration of hydrogen cyanide in low melting eutectics has been proposed[3]. These purines are also obtained from solutions of cyanogen (unpublished). The pyrimidines, however, have provided a more difficult problem. Uracil has been obtained from malic acid and urea, but only by heating in the presence of concentrated sulphuric acid[4] or polyphosphoric acid[5]. Low yields of uracil have been inferred from spectral data for a reaction involving acrylonitrile, urea and ammonium chloride[6]. Further details concerning the conditions of this reaction, however, have not been offered. Cytosine and, indirectly uracil, have been prepared from cyanoacetylene and cyanate[7,8]. The rapid hydrolysis of these reactants raises doubts about this route. Cyanoacetaldehyde, a hydrolysis product of cyanoacetylene, condenses with guanidine in aqueous solution to yield 2,4-diaminopyrimidine, which is hydrolysed to cytosine and uracil. The later route is considered to be more plausible[9]. Thymine has been prepared in 0.1% yield from uracil by a hydroxymethylation–reduction sequence involving formaldehyde and hydrazine hydrate in ammoniacal solution[10]. In view of uncertainties concerning the abundances on the primitive Earth of a number of the precursors which have been used in these studies, it seemed desirable to consider alternative routes to the synthesis of pyrimidines. In this report we describe the synthesis of uracil by the photodehydrogenation of 5,6-dihydrouracil (DHU), as well as the synthesis of DHU from β-alanine and urea in mild conditions.

β-Ureidopropionic acid (UPA), which is readily formed from β-alanine by reaction with urea[11] or with cyanate[12,13], is known to cyclise to DHU. The cyclisation is catalysed by acid[12], although certain substituted derivatives have been cyclised by heat[14]. We have found that the cyclisation of UPA can be affected by heating at moderate temperatures. UPA (2 g) in 20 ml H₂O was added to 25 g silica gel (Merck Kieselgel 60) and the water evaporated *in vacuo*. The mixture was then heated at 65 °C under N₂ for 5 weeks. DHU was isolated by column chromatography on cellulose in butan-2-ol–water (86 : 14) and characterised as *N*-acetyl-5,6-dihydrouracil (207 mg) by mixed melting point and infrared spectroscopy[15]. We have observed that the cyclisation of UPA to form DHU is promoted by urea. The direct evaporation of dilute solutions of β-alanine and urea either alone or in the presence of various silicates also results in the formation of DHU in the temperature range 60–90 °C. Further details of these experiments will be reported elsewhere.

In a typical photodehydrogenation experiment, 50 mg DHU in 5 ml hot distilled water was added to 1 g support material (Table 1), contained in a borosilicate tube (160 × 50 mm). The tube was equipped with inlet and outlet side arms for N₂ purging and a ground-glass joint for insertion of a Hanovia low-pressure mercury arc lamp. The tube was fitted to a rotary evaporator and the slurry evaporated and deposited on the walls of the tube *in vacuo*. Irradiation was carried out under N₂ for 48 h. The effect of water vapour on the reaction was tested by passing the N₂ through a flask filled with distilled water or, alternatively, through KOH. At the end of the irradiation period, the material was extracted with 100 ml hot distilled water and filtered. The products from these experiments gave
Fig. 1 Postulated pathway for prebiotic formation of uracil.

positive Wheeler–Johnson tests[16]. The presence of uracil was confirmed by ultraviolet absorption spectroscopy and by thin-layer chromatography on silica gel (*n*-butanol–acetic acid–water; 3 : 3 : 1) and on cellulose (*tert*-butanol–methyl ethyl ketone–water–concentrated NH₃, 40 : 30 : 20 : 10). Products from a number of experiments were pooled, and uracil was isolated by preparative thin-layer chromatography on cellulose as described above. Acetylation gave *N*-acetyluracil, as shown by comparison with an authentic sample by infrared spectroscopy and mixed melting point[15]. Quantitative analysis of uracil was carried out by ion-exclusion chromatography on Aminex A25 and A6 columns as described previously[17,18].

Results are summarised in Table 1. In the absence of added support, 2% conversion of DHU to uracil was obtained after

48 h. In the presence of montmorillonite number 20, however, the yield of uracil was 22%. This difference, as well as the influence of water vapour on the yields, suggests that the most active materials exert an effect by binding water in the solid phase and perhaps catalysing its photolytic dissociation. (Irradiation of DHU in aqueous solution also yielded uracil. After 4 d a 7% yield was obtained from a 0.0044 M solution.) Destruction of starting material and/or product was also more severe in the presence of water vapour. Thus, in the experiments with montmorillonite, uracil + DHU accounted for 90 to 97% of the starting material in the absence of water vapour, but only 74 to 82% in its presence. The series—montmorillonite, illite, vermiculite, kaolinite—is particularly interesting, as it represents a transition from expandable lattice structure

(montmorillonite) to non-expandable (kaolinite)[19]. A plausible mechanism for the photodehydrogenation might involve dissociation of bound water molecules and the hydroxylation and subsequent dehydration of DHU. The mechanism may therefore be similar to that involved in the ⁶⁰Co γ radiolysis of DHU, in which 5-hydroxy-, 6-hydroxy- and 5,6-dihydroxy DHU are formed[20]. Studies on the γ radiolysis of dihydrothymine have also implicated the OH radical as the reactive species in the formation of thymine[21]. Our studies on the mechanism of the catalysed photodehydrogenation are continuing.

We suggest that the synthesis of uracil by the reaction sequence shown in Fig. 1 represents a reasonable prebiotic pathway. Urea has been repeatedly suggested as a prebiotic reagent[22]. As the product formed in highest yield from solutions of hydrogen cyanide as well as by other pathways, it is one of the most plausible nitrogen-containing prebiotic materials and has been proposed as a possible storage form for ammonia on the primitive Earth[23]. β-Alanine has been reported in the Murchison meteorite[24], and has been formed in a number of simulated prebiotic syntheses[25-27]. Its abundance relative to other amino acids varies depending on the conditions chosen. In our proposed pathway, β-alanine would probably have been limiting. The entire pathway of carbamylation, cyclisation and photodehydrogenation may have occurred in evaporating pond environments, particularly where cycles of dehydration and rehydration were common.

Effect of point-freezing on ethylene and ethane production by sugar beet leaf disks

THE site of biosynthesis of the plant hormone ethylene in the cells of higher plants is unknown. Efforts to identify the enzyme system responsible and its subcellular location have failed because ethylene-producing plant tissues stop pro-

duction after homogenisation. On the other hand, ethane is produced as the main hydrocarbon gas after homogenisation of certain tissues of higher plants[1,2]. We have investigated the influence of point freezing on ethylene and ethane synthesis by sugar beet leaf disks, and found that both are stimulated.

Rates of ethylene and ethane formation were monitored after incubation of untreated or point frozen leaf disks of 23 mm diameter and about 100 mg fresh weight, in order to show that sugar beet leaf tissue behaves as theoretically expected[1,2]. The disks were cut from the upper third of sugar beet leaves not more than 12 weeks old, and floated on 1 ml of water in 3-ml Fernbach flasks, closed by a serum rubber stopper. After 2 h of incubation at 25 °C in the dark, 0.5 ml of the gas phase was analysed for ethylene and ethane by gas chomatography (compared with authentic gases purchased by Messer-Griesheim GmbH, Dusseldorf) as described before[3].

Table 1 Ethylene and ethane production of untreated and pressed sugar beet leaf disks

	Ethylene (a)	Ethane (b)	Ratio a/b
	(pmol per h per g fresh weight)		
Untreated disks	379±355 (61)	1±3 (35)	95±320 (35)
Pressed disks	33±171 (41)	86±40 (60)	0.4±2.6 (41)

Results are mean ±s.d. Figures in parentheses are numbers of experiments. These data were compared by statistical methods (t test, F test). Rate of ethylene production of untreated disks > pressed disks (P<0.01). Rate of ethane production of pressed disks > untreated disks (P<0.01). Ratio a/b of untreated disks > pressed disks (P<0.01).

The most ethylene was formed by untreated leaf disks (Table 1). Production of ethylene was strongly reduced after the leaf disks had been pressed with a plastic piston on a plastic board. In contrast, ethane production was low in untreated leaf disks and was strongly stimulated after pressing. These results, obtained by pressing sugar beet leaf disks, are in good agreement with results obtained after homogenisation of various higher plant tissues[1,2].

The following experiments demonstrate a correlation between the extent of wounding and the rates of production of ethylene and ethane by sugar beet leaf disks. For this purpose, leaf disks of 5-week-old sugar beets were frozen to various extents: a stainless steel rod, 3 mm in diameter, kept at the temperature of liquid nitrogen, was touched to the surface of the leaf disks for 2 s. This resulted in a frozen circular area of approximately 3% of the total leaf disk area. By repeating this process, leaf disks were point frozen to 25, 50, 75 and 100% with respect to the total leaf disk area and were then incubated as described above. Figure 1 shows the rates of ethylene and ethane production plotted against the percentage of frozen leaf disk areas. Production of ethylene increased as the extent of point freezing of the total leaf disk area increased from 0 to 50%, and decreased linearly as the frozen leaf disk area increased from 50 to 100%.

In contrast to ethylene, ethane formation increased linearly as the point freezing of the total leaf disk area increased from 0 to 100% (Fig. 1). The measured ethylene to ethane ratios plotted against the percentage of frozen leaf disk area (Fig. 2) shows a strict logarithmic dependence.

The linear stimulation of ethane production after leaf disk point freezing up to 100% of the disk area indicates that, in contrast to ethylene, ethane production is not dependent on intact compartmentalisation in the leaf cells, but rather depends on cellular disorder. Thus, ethane production and the ethylene to ethane ratio can be taken as an indicator of the integrity of sugar beet leaf tissue.
Fig. 1 Dependence of ethylene (○) and ethane (●) production on the percentage of frozen leaf area. Point freezing and incubation were achieved as described in the text. The points of the lines represent the mean of five experiments.

The influence of freezing on ethylene production seems to be more complex. Up to a certain extent of point freezing (in our case 50% of frozen leaf disk area), ethylene production increased after point freezing in spite of the decrease of unfrozen leaf area. When 50% of leaf disk area was frozen, further point freezing severely decreased ethylene production to an almost negligible amount. Assuming a K_m for O_2 of 0.2% for ethylene synthesis[4], the decrease of ethylene production and the concomitant increase of ethane production cannot be attributed to oxygen depletion as the result of an increased oxygen consumption after point freezing. This can be concluded from the observation that pressed leaf disks of 100 mg fresh weight consume about 1.6 μmol of O_2 per 2 h,
Fig. 2 Dependence of the ethylene to ethane ratio on the percentage of frozen leaf area. Point freezing and incubation were achieved as described in the text. The points of the lines represent the mean of five experiments.

representing 8% of the total amount (20.0 μmol) of O_2 available. From the above results we conclude that ethylene formation—in contrast to ethane formation—occurs in the leaf area surrounding the frozen parts of the leaf, representing a wound response of the non-decompartmentalised, but physiologically perturbed[5,6] cells, adjacent to the decompartmentalised (killed) cells.

If the percentage of the decompartmentalised tissue was increased, the non-decompartmentalised, but perturbed tissue was reduced, this being observed as a decrease in ethylene production.

The physiological role of the stimulation of ethylene production after wounding can be seen in the induction of wound responses, for example, the accumulation of phenolic compounds[7]. It is thus interesting that injury-related biosynthesis of an aromatic phytoalexin (phaseollin) in *Phaseolus vulgaris* has also been described to be dependent on living tissue adjacent to the injuries[8]. Ethane production, on the other hand, does not depend on intact tissue but rather on cellular disorder and loss of compartmentalisation, for the highest production rates are obtained with 100% frozen leaf area. Because of this independent behaviour of ethylene and ethane production, two different pathways can be assumed for their biosynthesis.

Errata

In the article "Significance of impulse activity in the transformation of skeletal muscle type" by S. Salmons and F. A. Sréter (*Nature*, **263**, 30; 1976), the tenth line from the bottom of the first column on page 33 should read . . . soleus muscles which had received stimulation showed light- . . . and not as printed.

In the article "Opposing effects of cyclic AMP and cyclic GMP on protein phosphorylation in tubulin preparations" by I. V. Sandoval and P. Cuatrecasas (*Nature*, **262**, 511; 1976) the pH value given in the second line of the legend to Table 1 should read pH 6.75 and not 7.65 as printed.

matters arising

Green rust: a pyroaurite type structure

McGILL, McENANEY AND SMITH[1] have described a green corrosion product of iron developed in water containing NaCl, K_2SO_4, $NaCO_3$, mixtures of these salts, and NaOH under various degrees of aeration. The X-ray data they reported indicate that the product is a member of the pyroaurite group[2-4]. In fact, Stampfl[5] and Taylor[6] have also concluded that a ferrous-ferric green rust material belongs to the group of pyroaurite structures.

We have been concerned[7] with the synthesis of products similar to the mineral takovite which has a formula of the pyroaurite type near to $(Ni,Mg)_6$ $(Al,Fe^{3+})_2(OH)_{16}CO_34H_2O$. We find that such products are formed readily in solutions containing Cl^-, NO_3^- and SO_4^{2-} ions, provided that CO_2 is not rigorously excluded. When water in its normal state or saturated with CO_2 is used, the same or similar final product is obtained. The presence of the anion CO_3^{2-} is shown unambiguously by infrared spectroscopic data. We suspect that other anions play only a small role in the formation of the product when CO_3^{2-} ions are present. For reasons which are not entirely clear, the pyroaurite structure type seems to form very readily when CO_3^{2-} ions are available. Possibly the planar nature of the CO_3^{2-} ion and the total number required are favourable factors; NO_3^- ions, although planar, must be twice as numerous for electrical neutrality.

Using the X-ray data reported by McGill, *et al.*[1], we have recalculated the unit cell parameters using the refinement program of Evans *et al.*[7]; the results are: $a = 3.166 \pm 0.001$, and $c = 22.52 \pm 0.01$ Å —values which are close to those given by McGill *et al.* and also by Stampfl[5]: $a = 3.17$; $c = 22.8$ Å.

It is of interest to consider a possible relationship between cation composition (as indicated by the weighted mean cation radius, $\bar{r}$), and the hexagonal a parameter. Figure 1 shows such a plot with data taken from the literature, including two unpublished points (G.W.B. and D.L.B.), dealing with takovite. The $\bar{r}$ values are calculated using the crystal radii of Shannon and Prewitt[8]. The smallest value of $\bar{r}$ is for takovite (G.W.B. and D.L.B., unpublished) and the largest for the green rust studied by Butler and Benyon[9] on the assumption of a 3 : 1 ferrous-ferric ratio. The available data cluster near to a
Fig. 1 Plot of $\bar{r}$ (mean cation radius), against unit cell parameter a for pyroaurite-type structures. Vertical line indicates the a parameter of the green rust of McGill *et al.*[1].

straight line and indicate for the green rust of McGill *et al.* a ferrous-ferric ratio of about 2:1; the precise result depends on how the line is drawn. In future studies of pyroaurite group materials, it will be useful to have chemically analysed materials and accurate cell parameters so that a composition-cell parameter graph can be drawn with greater accuracy than is now possible.

AN extraordinary orientational relationship between the rhombohedral green rust (with hexagonal unit cell dimensions $a = 3.181$ Å and $c = 21.82$ Å) and magnetite (cubic with $a = 8.434$ Å)— namely, $[1\bar{1}1]_{rh}$ or $[42.\bar{1}]_{hex}$ // $[1\bar{1}1]_{cub}$; and $(566)_{rh}$ or $(1\ 0\ \bar{1}\ 17)_{hex}$ // $(1\bar{1}1)_{cub}$—has been reported by McGill, McEnaney and Smith[1]. I should like to query this result, and to suggest that there is really no evidence that the relationship is other than $[00.1]_{hex}$ or $[111]_{rh}$ // 111_{cub}, and $(30\bar{3}0)_{hex}$

or $(2\bar{1}\bar{1})_{rh}$ // $(112)_{cub}$, as would be expected from a comparison of the oxygen packings of the two structures.

If the material is not well crystallised, or the platelet is very thin, the reciprocal lattice points will be extended parallel to $[00.1]_{hex}$ and it will not then be necessary to postulate that the diffraction spots, visible in their Fig. 1 and obtained when the beam is perpendicular to the crystal flake, have indices which strictly obey the requirement $-h + k + l = 3n$. The photographs reproduced in ref. 1 do not seem to show departures from hexagonal symmetry. Moreover, the hexagonal and rhombohedral cell dimensions are not entirely consistent with each other and the sets of planes considered to be equivalent do not really have similar d-spacings.

The simpler topotactic relationship had been reported earlier[2,3] but, together with work on the structure of the green rust materials[4], had gained inadequate publicity.

3 Lea, S. G., thesis, Univ. London (1968).

McGILL ET AL. REPLY—Mackay's argument[1] presumes that there is close matching of oxygen ions in the green rust and magnetite structures resulting from a topotactic transformation, that is, internal atomic displacements resulting in accord in three dimensions between initial and final lattices[2]. There is no conclusive evidence for this type of transformation from our experiments on the corrosion of cast iron. It has been found that magnetite and green rust usually precipitate from solution independently of each other, although there are isolated examples of the epitaxial growth of magnetite on green rust from solution. Figure 3 of our original contribution[3] illustrates this, and shows magnetite as three-dimensional, 'island' outgrowths from the surface of green rust crystals, a morphology commonly observed in epitaxy. Close matching of oxygen ions between green rust and magnetite is not, therefore, a necessary condition, since epitaxy can occur with large degrees of atomic

mismatch between substrate and overgrowth[4].

The orientation relationship that we report results from a correlation of *d*-spacings from electron diffraction, and the more accurate *d*-spacings from X-ray diffraction; such a correlation cannot be obtained if the orientation relationship proposed by Mackay[1] is assumed. Nor is there evidence to postulate a relaxation in the Laue condition, since scanning electron microscopy (see Fig. 3, ref. 3) indicates that the green rust crystals are ~ 0.1 μm in thickness or greater. The elongation of diffraction spots is usually associated with microcrystals which have critical dimensions of much less than 0.1 μm. Electron diffraction suggests that the green rust platelets are well-crystallised. An inspection of the rhombohedral unit cell shows that a flat crystal with a $(5\ \bar{6}\ \bar{6})$ habit plane may have hexagonal geometry.

Turning to the point raised by Brindley and Bish[5]: in our experiments green rust is grown in closed vessels by the corrosion of cast iron in solutions which are deoxygenated by purging with nitrogen. Thus the level of dissolved carbon dioxide is very low in non-carbonate solutions. For example, green rust and magnetite were formed by the corrosion of cast iron at 50 °C in distilled, deionised water containing 0.4 p.p.m. of oxygen. Chemical analysis of the water gave the following results: before corrosion, $pH = 7.4$, alkalinity $= 5.0$ p.p.m.; after corrosion, $pH = 6.6$, alkalinity $= 5.5$ p.p.m.; alkalinity $= [CO_3{}^{2-}] + [HCO_3{}^-] + [CO_2] + [OH^-]$. Since, for H_2CO_3 at 50 °C, $K_1 = 5.19 \times 10^{-7}$ and $K_2 = 6.73 \times 10^{-11}$ (ref. 6) the bicarbonate ion is the predominant species in this *p*H range, and the carbonate ion concentration is extremely low.

In another experiment, green rust produced in sodium carbonate solution, $[CO_3{}^{2-}] = 200$ p.p.m. was examined using infrared spectroscopy. The presence of the hydroxyl group was clearly shown but the carbonate ion was not detected. In view of the comments of Brindley and Bish[5], a more extensive infrared spectroscopic investigation is being undertaken, but at present, our experiments do not support the view that the presence of the carbonate ion is particularly significant in the formation of green rusts by the corrosion of cast iron.

These and other points relating to processes involved in corrosion of cast iron will be developed elsewhere.

Production of heavy elements in neutron stars

CHECHETKIN and Kowalski[1] have proposed that the production of heavy elements in nature occurs by the ejection of matter from a neutron star surface. Their suggestion relies on the results of Chechetkin and Bisnovatyi-Kogan[2,3], who find such matter to be composed before ejection of 'jumbo' nuclei ($Z \gtrsim 160$; $A \gtrsim 640$). These results were derived using a highly uncertain extrapolation of binding energies into the extreme neutron-rich region and in the absence of fission. Their justification of the neglect of fission is based on a necessarily very crude estimate of fission lifetimes.

The nuclear stability against spontaneous fission is the result of a barrier in the potential energy curve of a nucleus as a function of deformation. In the framework of the macroscopic–microscopic method[4,5], the potential energy can be divided into two parts: (1) a macroscopic contribution that takes into account the smooth variation of the energy as a function of nucleon number and deformation, and (2) a microscopic contribution that includes shell effects which are significant only near the magic numbers for neutrons or protons. The macroscopic energy is calculated using the liquid-drop or droplet model of the nucleus, whereas the microscopic contribution is evaluated from the energy spectrum associated with an appropriate potential well.

As the proton number and the neutron excess of the nucleus are increased, the stability against fission resulting from macroscopic energy is reduced both by the increased repulsion of the Coulomb force with the addition of protons and by the decreased surface tension of the nucleus with the addition of neutrons. It is the rapid decrease of the macroscopic energy as a function of deformation that causes nuclei beyond the actinide region ($A \gtrsim 260$) to be unstable with respect to spontaneous fission. Beyond the actinide region, only strong single-particle effects near neutron or proton closed shells (as for the case of the superheavy island $A \simeq 298$, $N \simeq 184$, $Z \simeq 114$) can offer stability against spontaneous fission. In the immediate region surrounding the superheavy island, the fission barriers of nuclei are virtually non-existent[6].

Furthermore, in a neutron capture the neutron separation energy in the compound nucleus plus the kinetic energy of the incoming neutron easily lead to subsequent fission. Consequently, any process of successive neutron captures will be terminated by neutron-induced fission before significant spontaneous fission can occur. Recent calculations[6,7] of fission barrier heights and neutron separation energies in the *r*-process region indicate that the astrophysical *r* process

may well be terminated by neutron-induced fission in the mass region $A \sim 280$. It should, however, be pointed out that the exact point of this termination is very uncertain because of an extrapolation of surface-asymmetry and closed-shell effects from the region of known nuclei and because of the use of the Strutinsky procedure. The termination point may be somewhat higher ($A \sim 350$), consistent with the possible discovery of superheavy elements in pleochroic halo inclusions[8] and their production in a conventional *r* process[9]. In spite of the uncertainties of the calculations of fission barriers[6,7], we believe that the existence of nuclei as large as $A = 640$, $N = 480$, $Z = 160$ is definitely ruled out. We should also mention that similarly large nuclei had been predicted in equilibrium conditions in neutron star matter[10,11]. This, however, has also been conclusively shown to be incorrect[12–14]. In conclusion, the nuclear basis of Chechetkin and Kowalski's suggestion for the production of superheavy elements is unfounded although it may well be that these elements can be produced in an *r* process occurring in the surface material of neutron stars. Studies along these lines are under way.

reviews

Assuming the mantle of soothsayer

L. Knopoff

Earthquake Prediction. (Developments in Solid Earth Geophysics, Vol. 9.) By Tsuneji Rikitake. Pp. xvi+357. (Elsevier Scientific: Amsterdam, Oxford and New York, 1976.) Dfl.95; $37.95.

STRONG earthquakes hold such terror for unprotected populations that those capable of forecasting earthquakes with any degree of reliability whatsoever, have a ready and appreciative audience. Thus, earthquake prediction has been the business of psychics and astrologers for centuries. The unhappy consequences of recent severe earthquakes have inspired significant effort in four nations to spur science to assume the mantle of soothsayer. Government-sponsored prediction research has been undertaken on a major scale in the USSR (since 1949), Japan (1963), China (1966) and the US (1971). In these countries, concerted efforts have been made in what must be the first priority in any programme—obtaining base-line information. These activities have been carried out to varying degrees in each country by measurement of strains, geodetic measurements, observations of micro-earthquake activity, geomagnetic, geo-electric and elastic properties, and collection of geochemical information.

Each of the four programs has its own emphasis. Professor Rikitake has been a leader of the Japanese program, and writes as an authority eminently qualified to review the Japanese program. The longest chapter in the book (62 pages) is concerned with geodetic surveying methods for observing precursory deformation of the Earth's surface and summaries of observations of such deformation before a number of earthquake events. Although geodetic observations are comparatively lightly emphasised in the other programs, they are a cornerstone of the Japanese national program.

The reader should not expect to receive a broad exposure to the basic problems of earthquake prediction or to the arguments and uncertainties that pervade the subject. Instead, this book provides a thorough review of the phenomenology of observations deemed pertinent to prediction. The reader who expects to derive understanding of the processes that underly the observations should look elsewhere.

The physical basis of earthquake prediction is unsatisfactorily treated. The shortest chapter in the book (4 pages) is concerned with the dilatancy model of the focal zone; in this model, the volume of matter increases due to the formation of small cracks shortly before rupture. Dilatancy is the only physical model proposed so far that has the promise of providing an understanding for the various precursory phenomena. Professor Rikitake withdraws from a detailed discussion of dilatancy, including the controversy over the role of water as an active agent in the dilatancy process.

The lengthy chapter entitled "The Theory of Earthquake Prediction", has no theory therein, but is concerned instead with statistical approaches to earthquake prediction plus an extensive catalogue of the events for which precursors have been observed. Two or three pages of the book are devoted to the phenomenology of brittle fracture and strike-slip processes; nothing is presented describing the physical basis in fracture mechanics for the earthquake event.

The book is well written in language understandable to the non-expert. The non-idiomatic use of the English language is not offensive. The editing and the selection of topics make the book a highly personal view of earthquake prediction. Major aspects of the topic deserve to be presented more broadly than is done here. In spite of extraordinary omissions, this book is useful for the extensive tabulations of observations of diverse precursory phenomena. ☐

L. Knopoff is Professor of Geophysics at the Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California.

Magnetic resonance techniques

Magnetic Resonance of Biomolecules: An Introduction to the Theory and Practice of NMR and ESR in Biological Systems. By P. F. Knowles, D. Marsh and H. W. E. Rattle. Pp. 343. (Wiley-Interscience: New York and London, May, 1976.) Cloth £9.75, $19.75; paper £4.25, $8.75.

THE applications of magnetic resonance techniques to biological problems are now of sufficient importance to merit inclusion in any well-balanced undergraduate degree course in biochemistry or biophysics. Although there are several specialist books dealing with such applications there has been no text written primarily for the undergraduate student.

Drs Knowles, Marsh and Rattle have now produced such a book dealing with the applications of nuclear magnetic resonance (NMR) and electron spin resonance (ESR) spectroscopy to biological problems. On the whole, they have produced a very useful book for both student and teacher alike. The parts of the book dealing with ESR are particularly valuable because such teaching material is not easily accessible elsewhere.

The basic theory of NMR and ESR are discussed together in an opening chapter and other chapters deal with the spectral parameters, practical aspects and biological applications of each technique. The carefully selected material is presented in an interesting manner and due emphasis is placed on the advanced experimental techniques which are required for successful biological studies. In general the theoretical aspects have been dealt with adequately although I would have preferred to see the theory of NMR and ESR introduced separately. In the NMR section a more detailed account of chemical exchange and relaxation behaviour would have been useful in view of the importance of these aspects of the theory in biological studies.

In some of the examples it was not always clear how the biological information had been derived from the NMR data. For example, a conformational structure for oxytocin was presented but none of the NMR argu-

ments leading to this were given. Obviously in a text of this type the authors have had to be very selective in their choice of examples of the numerous applications; they have succeeded admirably in finding examples which illustrate the scope of the techniques as well as providing interesting biological information.

The text would have been improved by including some consideration of conformational studies of small molecules of biological interest using spin–spin coupling constants and some studies of ligand binding to proteins. In general however the authors have provided an impressive coverage of the major areas of application including studies of protein and transfer RNA conformations and structures, protein unfolding, protein–protein interactions, protein hydration, metalloproteins, spin-labelled proteins and studies of phospholipid membranes.

This book can certainly be recommended to students and teachers wishing to learn more about the usefulness of magnetic resonance techniques in biology.   **J. Feeney**

Dr Feeney is a member of the scientific staff in the Division of Molecular Pharmacology at the National Institute of Medical Research, London, UK.

Immunology of reproduction

Immunobiology of Trobophlast. (Clinical and Experimental Immunoreproduction, 1.) Edited by R. G. Edwards, C. W. S. Howe and M. H. Johnson. Pp. x+284. (Cambridge University: Cambridge, London and New York, August 1975.) £6.

THIS volume represents the papers and discussion of a meeting held in January 1974 in the Physiology Laboratory, Cambridge, UK, and is the first of a series of meetings held on specific topics of immunoreproduction in association with the activities of the International Coordination Committee for the Immunology of Reproduction. All the participants were either British or were visiting Britain.

The papers all, in one way or another, address themselves to the key fact that the foetus is able to survive in the uterus in spite of the antigenic disparity which by rights should lead to its rejection as an allograft. Papers by A. C. Allison, by M. H. Johnson, by K. D. Bagshaw and S. Lawler, and by W. P. Faulk *et al.* document the complex antigenicity of the developing trophoblast, placenta and foetus. Details of trophoblast differentiation are described by R. L. Gardner and by W. D. Billington. The trophoblast and placental function in prevention of cell traffic and transfer of antigens and antibody is discussed by M. Adinolfi, whereas endocrine effects on the immunological consequences of implantation of the antigenically foreign foetus are described by R. Borland *et al.* W. R. Allen reports on the complex endocrinological and immunological features accompanying implantation and foetal development in the mare. Two extensive papers, one an overview of lymphocyte physiology by C. W. S. Howe, the other a review of the complex and often divergent observation on the effect of antigenic disparity on placental size, implantation and embryonic survival of mammalian embryos by A. McLaren complete the volume.

It is remarkable that in spite of the limited number of papers, the volume represents well the current state of knowledge in this field. The more comprehensive papers are doubtlessly the most valuable in that they focus in depth on the problems of trophoblast immunobiology, and in depth consideration of such problems is a luxury permitted all too infrequently in a time of increasing page charges and decreasing page allowances. The additional feature of publishing the discussion comments following each paper is especially welcome, for it provides the reader with a feeling for the current state of acceptance of or disagreement with the views expressed by the authors.

The volume is a most valuable addition to the literature in the fields of reproductive biology and of immunology.   **Robert Auerbach**

Robert Auerbach is Professor of Zoology at the University of Wisconsin, Madison, Wisconsin.

Membrane series

Biological Membranes. Vol. 3. Edited by Dennis Chapman and Donald F. H. Wallach. Pp. x+362. (Academic: London and New York, May 1976.) £11; $27.75.

WHEN *Biological Membranes, Physical Fact and Function* was published in 1968 there was no indication that it was to become volume 1 of a series which has now reached volume 3 and seems likely to continue. The publication of such volumes at irregular intervals of several years tends to delay some of the contributions unfairly and to provide an irregular and unpredictable coverage of the field. Nevertheless, in the book under review, the editors have collected together a group of six interesting topics and appropriate authors, most of whom seem to have written their contributions during 1974. The chapters are, in general, authoritative and well presented, and on such a variety of topics as to provide something of interest for everyone. Most libraries and many individuals may therefore be persuaded to continue to collect the series.

Two of the new topics, concerned with neutron diffraction and scattering and with the use of lanthanides to probe the role of calcium in membranes, are still at the exploratory stage and are reviewed largely to emphasise their potential for membrane studies. Other chapters discuss lipid and protein mobilities in membranes and the exchange of lipids between membranes and lipoproteins. The two remaining chapters provide a comprehensive review of nuclear membrane structure and function, and a specialist assessment of the specificity and significance of interactions between plasma membranes and gammaglobulins. The author index is four times as long as the subject index even though the latter includes all but three of the rare earth elements (all listed on p154).   **J. B. Finean**

Dr Finean is a Reader in Molecular Biology in the Department of Biochemistry at the University of Birmingham, UK.

Light scattering

Dynamic Light Scattering. By Bruce J. Berne and Robert Pecora. (Wiley: New York, March 1976.) £14.00; $27.70.

CLOSELY following the introduction of the laser we have in recent years witnessed a considerable increase in the number of original publications and review articles on light scattering theory and its applications to chemistry, biology and physics. The novel feature which transformed classical light scattering into a modern field of study was the possibility of undertaking dynamic studies over an extensive range of time and frequency scales. Not all expectations have been fulfiled; the study of chemically reacting systems for instance has been rather disappointing so far and the successful extraction of higher order information, beyond the derivation of translational diffusion constants in dilute macromolecular solutions, has been the rare exception rather than the commonplace event.

From the book under review, as well as from its recent predecessor (see *Nature*, **255**, 90, 1975) we learn that sufficient time has not yet elapsed to place the whole field into proper perspective. This reviewer would have been grateful for a logical development of modern scattering theory comprising the phenomenological, electromagnetic and molecular aspects. The authors are eminently qualified for this undertaking. They present a welcome wealth of theoretical derivations, sometimes on a very elementary and at other times on a rather advanced specialised level. Interspersion of a large number of applications from many different fields detracts from the general purpose. Whereas the theory could easily have been presented as a permanent whole, the applications are fragmentary and ephemeral, and can only be fully appreciated by reference to the original works. The thread is broken and the consistency lost.

There are a number of details which I believe can be easily corrected in a future reprint. Some terms and names are misspelt, some references in the text are incomplete, and some references are given as 1974 and 1975 as being in press—in a book published in 1976. A glossary of symbols would have been helpful in view of the complicated nomenclature. To find out which diffusion coefficient is determined in the light scattering experiment the reader must struggle through the whole development of non-equilibrium thermodynamics taken from another source.

In spite of the above reservations, this book will be useful as a sourcebook of important theoretical information in specialised research laboratories active in a wide range of scattering studies. **Henryk Eisenberg**

Henryk Eisenberg is a member of the Polymer Department, The Weizmann Institute of Science, Rehovet, Israel.

Pion–pion interaction

Pion-Pion Interactions in Particle Physics. By B. R. Martin, D. Morgan and G. Shaw. Pp. xi+460. (Academic: London and New York, May 1976.) £16; $40.50.

AT some time during their career, most high energy physicists must obtain some acquaintance with the pion-pion interaction, because of its pervasive nature in hadronic physics. In future, I will have no hesitation in recommending the appropriate chapter of this book to them as an essential reference. The book provides a timely review of the subject, as there have been many important developments, both experimental and theoretical, since the appearance of Petersen's comprehensive *Physics Reports* article in 1971.

The lack of real pion targets means that special techniques have been developed to extract data on $\pi\pi$ scattering. A substantial part of this book is devoted to a careful explanation of these methods and the results from recent high precision experiments. The other major section of the book deals with theories and models of $\pi\pi$ scattering.

In places the book inevitably reflects the authors' own approach to the field. It is, for example, somewhat surprising that explicit expressions for the S and P wave contributions to the important Roy equations are not included in the otherwise extensive appendices. In general, however, they are to be congratulated on the care they have taken in preparing this book, which is destined to become a standard reference and should be available in all high energy physics libraries. **C. D. Froggatt**

Dr C. D. Froggatt is a Lecturer in the Department of Natural Philosophy, Glasgow University and has made many contributions to the phenomenology of pion–pion scattering.

obituary

Nikolai Ivanovich Muskhelishvili the eminent mathematician died on July 16. He was born on February 16, 1891 into a remarkable family, of great renown in Georgian history. His father, Ivan Levanovich, was a General in the Engineering Corps of the Imperial Russian Army, and had interesting ideas on the education of children. He spent a good deal of time teaching his own children—particularly 'Niko' whose mathematical ability he recognised at an early age. Muskhelishvili's mother, too, was a person of great culture as well as charm.

After completing his secondary education at the Second Tbilisi High School, Muskhelishvili entered the Faculty of Physics and Mathematics of the University of St. Petersburg in 1909. His outstanding ability early attracted attention, and legends were soon circulating among the student body of the accomplishments of the remarkably gifted young Georgian. He graduated in 1914 and in the following year presented a diploma thesis of such merit that he was invited to become research assistant to Gurii Vasil'evich Kolosov, a pioneer in the application of function theory to plane problems in elasticity. It was Kolosov who guided Muskhelishvili's first steps in the subject which in the next sixty years he was to revolutionise and dominate, and, in the process, to influence critically much of the development of mathematics (both pure and applied) in the USSR. One of his first papers, *Sur l'intégration de l'équation biharmonique,* published in 1919, gave a foretaste of the simplicity and elegance which were soon to become the distinguishing features of everything he wrote. As with most of his later writings on elasticity, the problem considered was of great practical as well as mathematical interest, for a special case considered by Muskhelishvili proved to be basic to the theory of brittle fracture in thin plates.

In 1917 Muskhelishvili was appointed an assistant in what was now the University of Petrograd and two years later was promoted to an instructorship. It is typical of him that in the years 1915–1920 he gave a great deal of his time and energy to teaching in other institutions of higher learning in Petrograd which, because of the troubled times, were experiencing grave staffing problems.

When the university of Tbilisi was founded, he was invited to join the faculty. He returned to his homeland in 1920 and remained there until his death. Soon after his return to Georgia, Muskhelishvili assumed the role of leader of Georgian mathematics and created in Tbilisi one of the chief mathematical centres in the world. Initially, the group concentrated on the mathematical theory of elasticity, but later, comparable effort was put into important fields of analysis. Many of the famous names of Soviet mathematics appear in the records of the Tbilisi group and many more were influenced by the great stream of papers and research monographs which flowed from it.

Muskhelishvili's own research contributions were almost entirely in the theory of plane elasticity and in the theory of singular integral equations, but it was not only those branches of mathematics most directly connected with his own research interests that he sponsored. To take only one example: it was through his active support that the Georgian school of topology was founded and nurtured in its early years.

During this period of intense scientific activity extending over half a century, Muskhelishvili was tireless in his efforts to organise efficiently scientific activities in Georgia. He gave devoted service to the Academy of Sciences of the Georgian SSR, and from his election in 1939 as a full member of the Academy of Sciences of the USSR he served repeatedly on its Presidium. When the National Committee of the USSR for Theoretical and Applied Mechanics was established in 1957 he was the obvious choice for its Chairman and he served long in that capacity, with the representation of the USSR on various international bodies which that office involves.

Muskhelishvili was influential in wider circles than the scientific. Believing that a university professor should participate fully in the life of his country he was active in the political field; among the offices he held was Deputy of the Supreme Soviet of the USSR.

For his scientific work and for the significant role he has played in the development of Soviet science, Muskhelishvili received many awards and honours, from his own government and from foreign institutions. Those who were privileged to know him and his family values the memory of his friendship and his gaiety, recall with affection the delights of his companionship as much as his incisive judgment on scientific questions. Future generations will know him only from his research papers and his two great monographs *Basic Problems in the Mathematical Theory of Elasticity* and *Singular Integral Equations* which achieve the seemingly incompatible aims of creating a satisfying unified theory and at the same time pointing the way to new realms of enquiry.

In all his published work Muskhelishvili showed that he was both a pure and an applied mathematician. The 'applied' aspect of his nature was shown by his willingness to look at problems of real practical significance, the 'pure' in the rigorous analysis to which he subjected the problems thrown up by his investigations into mechanics.

I. N. Sneddon

Take your time, Mr Benn

LIKE a good thriller, the Royal Commission on Environmental Pollution's report on the environmental risks of nuclear power, published last week, gives relatively little away in its early chapters. With the greatest of care (and surely such a readable report deserves a wider audience than the Stationery Office is accustomed to delivering) the scene is set in what could serve as an intelligent layman's guide to nuclear energy. A little pat on the back here, a modest rebuke there; a new committee suggested, a possible gap in interdepartmental responsibilities pointed out. Then, with the end of the book almost in sight the action quickens—in a somewhat unpredictable way—and the final pages are highly controversial.

The commission, chaired for the duration of the preparation of this report by Sir Brian Flowers (though now headed by Professor Hans Kornberg), has as its remit to advise on environmental pollution, on research, and on future dangers to the environment. The projected growth of the civil nuclear power programme, with all the associated general concern over possible radiological hazards, stands out as an appropriate field of study for the commission, particularly with pressures growing for an early government decision on major investment in a demonstration commercial fast-breeder reactor (CFR). The report has come none to soon; authorisation to go ahead with the design for the first CFR—popularly known as CFR-1—was being sought from the Energy Secretary, Mr Benn, by the United Kingdom Atomic Energy Authority (UKAEA) within a matter of weeks. At least the publication of the report will give Mr Benn good cause to delay his decision. Careful analysis of the commission's arguments could conceivably persuade him that clearance for CFR-1 would be an unwise option. For the widespread implications of such commitment, even to just one CFR, will greatly overshadow even the implications, little realised at the time, of commitment to building Concorde.

At first glance the benefits of fast breeder reactors seem overwhelmingly attractive. All present-day thermal nuclear reactors are fuelled primarily by fissile uranium-235. Even so, non-fissile uranium-238 is by far the dominant isotope in the fuel elements, and thermal reactors convert some of this to plutonium-239 which, like uranium-235, is fissile. But only a small amount is converted. This is where fast breeder reactors steal an advantage: they "breed" more fissile material in the form of plutonium-239 than is lost in the form of uranium-235. Obviously, this requires a major rethink of reactor design. A high density of fast, rather than slow, "thermal", neutrons is required, and the reactor core must be very compact. Consequently, the starting fuel must be a mixture of plutonium and uranium. The engineering difficulties are not insuperable; already prototypes have been built or are under construction, not only in the UK, but also in France, the Soviet Union, the US, and West Germany. Full-scale, commercial fast breeders would probably run at above the 1,000 MW mark, would be cooled by liquid sodium, and would, after the initial charge of fissile uranium and plutonium, never need specially enriched fuel, being able not only to run on depleted fuel from thermal reactors but also to feed back fissile plutonium to thermal reactors. All of which looks immensely attractive as a medium term prospect for nuclear power stations.

Except for one catch : all the plutonium which will be around. By the early 21st century, according to some scenarios, the world will be geared to a plutonium economy, with the developed nations satisfying their energy requirements by using and circulating plutonium—a highly toxic metal quite easily convertible into nuclear weaponry. The commission accordingly devotes much of its attention to the problems that the plutonium economy throws up. It also, however, uses the opportunity of the report to review many other matters, such as radiological standards and waste management, which still needs serious attention regardless of any decision on the CFR.

The report first reviews what is known in radiobiology, with particular attention to plutonium. The present maximum permissible body burden is 0.6 mg, and the commission does not consider this standard to be seriously in error. In reaching this decision it had to consider the "hot particle theory", Gofman's analysis of the effects of smoking on lung clearance rates, and assertions that deaths from leukaemia among workers at the Windscale reprocessing plant in Cumbria were significantly high. For the first two, independent consultants were brought in, for the third the National Radiological Protection Board (NRPB) produced a paper, and, as a result, fears of any serious error in radiological standards were dismissed in every case. The consultants' reports have not been published nor even promised, and many will want to suspend judgment until they are openly available.

Next, the commission looks at how radiation standards are arrived at and enforced. The way that the International Commission on Radiological Protection reaches decisions is deemed satisfactory—the UK already fully accepts these standards. But there is some feeling that the NRPB, "a national point of authoritative reference in radiological protection", is not fulfilling a sufficiently central role, largely because it is fairly new while other bodies concerned with nuclear

power still have much in-house expertise. The commission recommends that consultation with the NRPB should become mandatory and that the NRPB should be statutorily responsible for endorsing basic standards. Further, the NRPB should provide the focal point for coordinating research into radioactivity in the environment, which is at present well done in the marine environment by the Fisheries Research Laboratory, but only patchily covered in the atmospheric and terrestrial environments. More work is also pointed towards the NRPB in the monitoring of radiation workers and of discharges.

If the comments on standards are relatively soothing, the pace of the report quickens a little when it comes to waste management. It is here, of course, that emotive issues—"leaving a radioactive time-bomb as a legacy for countless generations" and so on—could crop up. The commission asserts that "there should be no commitment to a large programme of nuclear fission power until it has been demonstrated beyond reasonable doubt that a method exists to ensure the safe containment of long-lived, highly radioactive waste for the indefinite future". It also makes it clear that the method does not yet exist. Lower levels of radioactivity are also considered and one or two comments made, particularly about the less than highest standards of housekeeping observed during the commission's 1974 visit to Windscale. But it is the high level wastes, mainly fission products, at present in tanks at Windscale which get most attention. Vitrification is seen as indispensible; development started in the late 1950s, but will not be commercially available until 1985 (there was a strange period of inactivity in the 1960s). Final disposal of the 15-tonne cylinders (a magnox reactor generates three tonnes a year in the UK) is the real problem.

The commission quickly rule out space rockets, subduction at ocean trenches, deep burial in Antarctica, and the time-honoured means of disposing of ships' waste—over the side. Burial is seen as essential, either on land or down specially drilled holes at sea. Surprisingly little research has been done in the UK on these options (maybe tHat is why they still seem attractive!), and the commission is critical both of UKAEA and British Nuclear Fuels Limited for their complacency. It proposes that a Nuclear Waste Disposal Corporation be formed to get on with the job.

The two issues that get most headlines in connection with plans for widespread nuclear development are the possibility of serious reactor accidents and the risk of illicit activities. In both of these fields the commission acknowledges itself to be straying well outside its brief, so its views can only really be those of a collection of very well informed laymen. Nonetheless, the chapters on these subjects, particularly on the latter, are important in that they provide a more total approach than is likely to appear in official discussions elsewhere.

Any assessment of the threat that terrorists could pose if a plutonium economy becomes established, or that security measures could pose to civil liberties is extremely difficult, and the commission rightly does little more than spell out some of the problems— it provides no cut and dried answers. On balance, the likely effects on civil liberties do not on the surface look serious in a generation used to all sorts of screening. But Sir Brian Flowers has already remarked that every wedge has its thin end, and even while the present arming of nuclear security guards must be seen as an eminently sensible move, the ultimate long-term implications need careful assessment. The terrorist threat looks more obviously bleaker. Would it be possible to site a fast-breeder in Northern Ireland? Is the rest of the UK immune from terrorist threats, bearing in mind that terrorist groups could be fed information by other states with nuclear capabilities? And the question is inevitably a world problem—if the UK opts for a plutonium economy it may significantly encourage other countries with less political stability to do likewise; even a terrorist attack in just one country would have worldwide repercussions. Still, the report carefully avoids judging these complex human questions, merely listing the potential dangers. But then, in a quite unexpected development, it proceeds to cast severe doubts on fast breeders.

The sudden switch comes in the chapter on energy strategy, and the argument runs like this. The Department of Energy (DEN) has made various energy demand forecasts for the next 50 years based on reasonable growth assumptions. In the most favoured current version electricity consumption more than trebles by 2025; sumption more than trebles by 2025: 104 GW of nuclear electricity are needed by 2000 rising to 365 GW 25 years later. The commission observes that emphasis on electricity ensures that
● There will be a huge call for investment in the energy sector (3.4% of GNP, as opposed to 1.4% today),
● A large number of coastal sites must be developed by 2030—a requirement that it may not be possible to meet,
● A lot of the primary energy converted will be wasted in the form of low grade heat.

In a couple of breathtaking pages the commission becomes merchant banker and declares itself "very doubtful" on the investment prospects, becomes the Fine Arts Commission and declares all these power stations a substantial adverse effect on amenity, and reverts to environmental commission to declare in three paragraphs that the heat might affect the climate. There thus appear "very considerable environmental objections to the high-nuclear, high-electric future". The feeling is rather as if a referee, after arbitrating over a goalless draw for 89 minutes, suddenly decides to boot the ball into the net to break the deadlock. Once the label "environmental objections" has been pinned on to one DEN scenario (although many other scenarios have been published—even down to a non-nuclear future) the rest of the report becomes coloured by a general optimism on alternative sources. Coal, of course, would bear the brunt of the load; and it is noticeable how the immense radiological protection lavished on nuclear workers is not matched by any comparable health concern for the miners who will have to dig the coal up.

One feels that with one hasty glance at 2025 the commission has made its mind up on the delicate issue of fast-breeder reactors—they should be introduced "only if demonstrably essential"; in the meantime money should be directed towards other technologies, notably fusion (though it is not clear that fusion research would benefit from a diversion of even a little of the £2,000 million that might eventually go into CFR-1), and international collaboration should be sought out for fast breeder development.

So where does this leave Mr Benn? The nuclear industry claims that it needs early decisions; the commission urges delay. Even though some of the commission's otherwise excellent reasoning is marred by sloppy thinking, the issues raised must give Mr Benn pause for thought. The question that undoubtedly is central in his mind is whether the technological momentum that will be built up by commitment to CFR-1 is stoppable if the warning bells begin to ring. Unless he can devise ways of ensuring this, and until the nuclear industry can demonstrate its understanding of the need for aborting mechanisms, he would do well to adopt a delaying strategy. The middle course steered by the commission makes one thing outstandingly clear: there is need for more discussion and a greater appraisal of the possibilities. Is an early decision on CFR-1 really as essential as the reactor itself may ultimately prove? The extra couple of months already gained since the report's publication (the DEN last week announced that the decision planned for October will now wait until at least the end of the year) must be seen to be more than just a token delay. □

Soviet dissidents (1)

He who would dissident be

Why do so many Soviet scientists become dissidents
and refusniks? **Vera Rich** considers the question

ONE of the paradoxes of contemporary Soviet 'opposition', whether it comes from dissidents proper, who campaign for improvement of the system from within, or from the Jewish refusniks, whose only wish regarding the Soviet Union is to leave it for Israel, is the presence of large numbers of those who might be expected to benefit most from the *status quo*—scientists. In a culture which bases its whole economic policy on the "implementation of the scientific technological revolution" and which, with its total state control of all resources, can allot virtually unlimited funds to a favoured research project, the position of a scientist, one might feel, is surely such as to ensure all the fringe benefits which Soviet society affords its elite—access to privileged shops, better housing, Black Sea holidays, and the like. Yet, by the kind of paradox which characterises so much of Russian history, it is partly this privileged position that has led to the development of dissidence among scientists.

The story begins back in the late 1940s when Stalin, having 'abolished' Mendelian genetics throughout the Soviet Union, and replaced it with the peculiar notions associated with the name of Lysenko, turned his attention to modern physics. Since the basic tenets of relativity theory and quantum mechanics seemed, in the opinion of certain favoured theoreticians, contrary to Marxism–Leninism, Stalin aimed to confine physics research to what was congruous with Newtonian mechanics. But a small group of physicists, notably Kurchatov, Kapitsa and Vavilov, managed to convince him that without modern physics he could expect neither nuclear power, nor, and this was the clinching argument, a nuclear arsenal. Modern physics was accordingly permitted to continue, although, until Stalin's death, textbooks were liable to contain face-saving clauses to the effect, for example, that the second law of thermodynamics was "a local phenomenon in this part of the universe".

Having protected their own discipline from destruction, it was perhaps natural that physicists should come to the aid of their less-fortunate scientific brethren, the harassed geneticists, in their fight to re-establish genetics as a valid field of research. Lev Tumerman, a physicist working on the luminescence of organic molecules, was instrumental in arranging the first

seminar on chromosomes, held in the Lebedev Physics Institute during the late 1950s, while in 1959, Timofeev-Resovskii gave his first genetics lecture in Kapitsa's Institute. And in the great debate of 1964, which finally crushed the attempted resurgence of Lysenkoism and re-established genetics as a branch of Soviet science (although it did not receive 'priority' funding for another 10 years), certain physicists, notably Andrei Sakharov, played a significant role.

From the defence of a single scientific discipline to a deep involvement with human rights as a whole is, however, a great step to take. But a number of factors in Soviet society established a climate for dissent. The phenomenon of *samizdat*—'do-it-yourself' publishing and distribution, to sidestep official censorship—reaches far back into the 19th and 18th centuries, and it received a new impetus with the mushrooming availability of typewriters and, on occasion, photocopiers. The education reforms of 1958 which, in effect, made Russian virtually the only language of higher education and academic life, produced great discontent among the non-Russian republics of the Union, notably Ukraine and the Baltic States. The highly anti-Israeli attitude of the Soviet media at the time of the Six-Day War for the first time impressed upon Jewish intellectuals an awareness that Israel was not merely a paper creation (on the lines of the Soviet 'Jewish homeland' of Biribidjan). Israel at last came to be seen as a viable alternative society where Soviet Jews might live and work unhampered by the many disabilities which (*de facto*, and in contradiction to the Soviet constitution) are still the lot of those with "Jewish nationality" stamped in their internal Soviet passport.

But *samizdat* was, originally, the province only of the more daring creative writers, while the problems of minority nationalities had always been endemic to the multinational Russian empire. And except in a few cases, such as the promising Ukrainian school of cybernetics, little was lost to Soviet research when the language of instruction and publication was officially changed—a scientist, after all, must expect to read and, on occasion, to publish, papers in languages other than his own. Why then this great participation by the scientists in the human rights movement and dissidence?

Kronid Lyubarsky, 5-year sentence

Andrei Sakharov, the acknowledged leader of scientific dissidence, has given his own account. Though he originally viewed nuclear balance as an important factor of world peace, he subsequently began, as early as 1958, to agitate for the cessation of nuclear testing. The reason for the switch was clear. He became convinced that no further benefits could be gained from such tests, believing that the sole outcome would be nothing more than an increase in the natural level of genetic hazard. The fundamental change of attitude undergone by Sakharov by the early 1960s led to his concern about the 'criminal nature' not only of the tests but of the whole concept of nuclear weaponry. Beset with a sense of helplessness he devoted an ever-increasing amount of time first to *samizdat* writings (the 1968 monograph *Thoughts on Progress, Coexistence, and Intellectual Freedom*, and the *Second Manifesto* of 1970), and later to appeals on behalf of fellow dissidents threatened or imprisoned for their views and activities.

There is no doubt that Sakharov's personal charisma became a major factor in drawing together the little group who formed his illicit 'human rights' movement, and its subsequent off-shoots—the Moscow branch of Amnesty International and the 'Helsinki monitoring' group. Among Sakharov's associates are such leading lights as the physicists Valentin Turchin and Andrei Tverdokhlebov, the mathematician Valerii Chalidze, and the biologist Sergei Kovalev.

But what of the many others who did not at first have any personal contact with the great names of the dissident world? Some general trends may be distinguished. First, many students turn originally to science not so much from a personal preference for the subject as such, nor from hopes of a prestige job, but because science offers the hope of academic freedom, so

patently absent from the humanities which are dominated by the hard-and-fast requirements of Marxist–Leninist ideology. This expectation may remain unfulfilled—Soviet medical students are often disillusioned with psychiatry and psychology lectures based on Pavlovian behaviourism and a rigid definition of what constitutes 'normality'. Moreover, even in the absence of such specific disillusionment, the Soviet scientific establishment itself produces an atmosphere of frustration.

Travel to conferences abroad (or even, in some cases, within the Soviet Union) is frequently blocked by barriers of officialdom open only to the favoured few. Foreign publications cannot be obtained on subscription and are often inaccessible in libraries except to those with special security clearance.

The classic story of frustration recounted in *The Medvedev Papers* is by no means unique. The Soviet system makes no allowance for serendipity—a frequent complaint from young researchers is : "They expected me to order all the equipment and reagents before I started, but if I'd known exactly what I wanted, I wouldn't have needed to do the experiment"; or, "The official supply system is useless. You can only get on if your laboratory has a good 'fixer' who can arrange a swap with someone who has what you need." (This latter difficulty leads to deliberate over-ordering and the development of a system of polygonal bartering, involving several laboratories at a time.)

Such frustrations may eventually lead scientists to work more actively for human rights, even at the cost of a secure career. Vladimir Bukovskii, a biology student expelled from Moscow University for his dissident views, became the first prominent campaigner to focus world attention on the misuse of psychiatry by a regime aiming to equate dissidence with insanity. At the very least the frustration which so motivated Bukovskii may lead to a state of mind describable as "passive dissidence", creating a ready readership for available *samizdat* material. It should be remembered, of course, that even the temporary possession of *samizdat* material is a serious offence. Biologist Nina Strokata-Karavan'ska, for example, served a four year sentence for possession, and is still exiled from her native Ukraine. Similarly, Sergei Kovalev, another biologist, is serving a 7-year sentence in a strict regime camp. (Kovalev, a member of the Moscow Amnesty group was curiously charged with possession of the illegal *Chronicle of the Lithuanian Catholic Church*, although he is neither a Lithuanian, nor, so far as is known, a Catholic). Even greater penalties can be involved. Astrophysicist Kronid Lyubarskii, is not only serving a five year sentence—

moves are now afoot to deprive him of his academic degree.

For a Jewish scientist, however, discontent typically results in an application to emigrate to Israel. (As a convenient one-way ticket out of the Soviet Union, this opportunity is occasionally afforded to troublesome non-Jews, such as Leonid Plyushch, the Ukrainian mathematician.) But emigration is by no means an easy option. Successful applicants often indicate that the obstacles placed in their way actually intensify their Jewish consciousness, so that Israel becomes a positive permanent goal rather than merely the only available sanctuary. Once an application is placed, a whole chain of sanctions are imposed. Job dismissal is virtually automatic—with a consequent long-term loss of access to all professional publications and loss of contact with new specialist developments. (It was in an attempt to maintain at least some semblance of scientific life that Aleksandr Voronel founded the famous Sunday seminars). The authorities can throw up a whole battery of reasons for refusing exit visas. These include military service (often invoked in the case of over-age invalids, such as Mark Azbel, Voronel's successor as leader of the Sunday seminars); security restrictions (even in fields where the Soviet Union is not noticeably ahead of, or even abreast with, developments elsewhere): and the notorious 'education tax' (waived since the Nixon visit to Moscow, but never actually revoked) which required the payment of an extortionate sum, allegedly equal to the estimated cost of an applicant's university and post-graduate studies.

Reprisals may extend to relatives. Metallurgist Evgenii Reinberg was expelled from the Communist Party, and subsequently from his academic post, when his son applied for a visa. Endocrinologist Mikhail Shtern, now serving an 8-year sentence for "accepting bribes", was actually told that the accusation was made "in connection with your family's desire to emigrate". And, of course, dismissal from one's job involves the constant threat of arrest for 'parasitism', or being without visible means of support, a threat directed particularly often, it appears, at the members of Azbel's seminar.

Needless to say, a refusnik scientist shares the same disabilities as a dissident where international conferences are concerned. The recent absence of Benor Gurfel from the European meeting of the Econometrics Society in Helsinki, and of Academician Veniamin Levich from the Annual Meeting of the International Society of Electro-chemical Scientists in Zurich, are cases in point.

'Active' dissidents and refusniks con-

stitute, however, only a small part of the Soviet scientific community—indeed, a main campaigning point for refusniks is that, since they are by no means irreplaceable, the Soviet Union can well afford to let them go. (Thus, such vocal and embarassing dissidents, as Chalidze, Zhores Medvedev, and mathematician Aleksandr Esenin-Volpin, have been forced into exile.) So what of the bulk of the scientific community?

The overwhelming majority of scientists, it may be said, seem to find relief from discontent and frustration in 'inside emigration'—a complete absorption with work (although even that is a kind of dissent, since, according to *Pravda*, "a scientist's first duty is to be a patriot", with all that patriotism demands in voluntary community service and attendance at meetings and hortatory or celebratory rallies). The silent majority is, as everywhere, completely silent. Nevertheless, the scientific establishment still preserves some vestiges of independence from the State. The Academy of Sciences is the only remaining body in the Soviet Union to exercise the right of elections by secret ballot without official intervention (though it must be admitted that its current President, Aleksandrov, was nominated by the Party, before being duly elected). In spite of periodic press campaigns against Academician Andrei Sakharov, and in spite of the refusnik status of Corresponding-Academician Levich, the Academy has not, so far, expelled either. A two-thirds majority is needed for expulsion, and the lack of action so far indicates a degree of uncertainty as to how far dissidence, or fellow-feeling for dissidents, might spread.

In this situation of frustration, it is small wonder that so many appeals, whether from dissidents or refusniks, call upon the world scientific community to take some action on behalf of harassed Soviet colleagues. The appeals are wide-ranging. Scientists in the non-communist world may be urged to plead for clemency for victimised Soviet scientists on trial. They may be urged to press for reviews of particularly harsh verdicts against those already convicted. Or they may simply be asked to request visas for specialists wishing to attend international conferences. A recent statement from the US Committee of Concerned Scientists stressed that these actions are more than gestures of common humanity towards distressed colleagues. When a scientist is for any reason prevented from working, the research he might have done is "irrevocably lost to science"; the fate of dissident and refusnik scientists affects not only Soviet science, but also the whole worldwide scientific community. □

Soviet dissidents (2)

Keeping the flame alight

Robert Adelstein participated in the Moscow Seminar earlier this year. Here he describes his experience

"THE West is serving as a witness to our scientific death. This is the whole point of the Soviet policy, to doom us forever as scientists". The speaker was Mark Azbel, head of the best known Moscow Seminar of dissident scientists. The words were the emotional highpoint of an impassioned closing speech delivered earlier this year during an extraordinary session of the seminar. For five days Hershel Markovitz, a Professor of mechanics and polymer science, and I, a biochemist, shared in the science, thoughts and experiences of the seminar members.

We had arrived in Moscow six days earlier not only to participate in the Moscow Seminar, but more important, to express the continuing interest of western scientists in their less fortunate colleagues. Any prior doubts we had about the impact of a visit by two relatively unknown scientists were quickly dispelled by the overwhelming reception we received. In honour of our arrival it was decided to hold a 'symposium' during which we would deliver three papers each and the Russian scientists would contribute ten of their own. We would meet every day for 3–4 hours of formal science followed by informal discussions about the status and problems of dissidents.

The Moscow Seminar on Collective Phenomenon, as it is officially known, convenes every Sunday at 12 noon in the sparsely furnished apartment of Mark Azbel. (It is one of six different seminars of dissident scientists convening in Moscow at present.) It comprises approximately 30 scientists drawn from various disciplines: physics, mathematics, cybernetics, electrochemistry, biophysics and molecular biology. But despite their differences in training the scientists all share one common attribute—they have applied for an exit visa to Israel and the visa has been refused. They are refusniks.

With very few exceptions refusniks are fired from their jobs and forced to eke out a living either by tutoring privately or by securing menial, non-scientific work. They are denied access not only to laboratories, but also to libraries, where their names are removed from published works, and where the books they have written are removed from the shelves. Reference by Soviet scientists to their published works is forbidden. They are denied official permission to publish scientific

papers in the Soviet Union or to mail them abroad to foreign journals (though papers can, of course, be smuggled out). Incoming mail, particularly from abroad, is interrupted. Telephones are often disconnected. Attendance at scientific meetings at home or abroad is forbidden. And refusniks are often ostracised by former colleagues and harrassed by the KGB. The price of applying for an exit visa is high enough to discourage many would be emigrants.

Yet occasionally, in a pattern that defies discernment, a refusnik is released. My first visit to the Moscow Seminar had been in August 1972, the year it was first organised by 15 scientists because of "an urgent fear that we would lose our scientific standing, together with the loss of our employment". The words were spoken by Alexander Voronel, at whose apartment the seminar was convened. Three years after applying for his visa, Voronel was permitted to emigrate and is now a Professor of Physics at Tel Aviv University in Israel.

I remember sitting in Voronel's apartment with Benjamin Levich—a refusnik, a corresponding member of the Soviet Academy of Science, and a world-renowned electrochemist—together with his two sons Alexi and Yevgeny. His sons now live in Israel—though Yevgeny, a physicist, was incarcerated for a year in an Arctic Circle prison camp before being granted a visa. But their father and mother still await visas, despite Soviet promises to release them in October 1975.

My latest visit, in late winter, started on a Friday in a Moscow still blanketed with snow. My arrival with Hershel Markowitz, earlier in the day, was uneventful except for an extremely thorough search of our luggage at customs. Interestingly, the only reading matter which aroused enough curiosity to require further perusal by a higher official was not a month's supply of *Nature* and *Science* along with assorted scientific texts, but a Moscow guide book published in 1974 in the USA. It was our sole encounter with Soviet officialdom.

Later that night I journeyed by subway to the apartment of Irene and Victor Brailowsky—she a mathematician and he a cyberneticist—both of whom are members of the seminar. Arrangements were made to notify the seminar of our arrival (no easy task

Victor Brailowsky, harassed and threatened

since telephone communication was not possible) and to meet on Sunday for the trip to Azbel's apartment, which is located on another side of the sprawling city.

Mark Azbel greeted us enthusiastically on our arrival at his apartment. The balding, red-haired leader of the group looks considerably older than his 43 years. His whole manner reflects warmth and a certain dynamic intensity which seems to inspire the group whether discussing science or politics. After our introduction to the group—most in their 30s and 40s and much younger than I had imagined, we were joined by Benjamin Levich. A schedule for the 'symposium' was quickly drawn up, it being agreed to meet in Azbel's apartment every evening at six o'clock with the exception of Wednesday, when we would meet at Levich's. This would allow us to meet with some physical chemists who only attended Levich's Wednesday seminar, and with Alexander Lerner, like Brailowsky a refusnik cyberneticist. In one of the best examples of how international cooperation among scientists can force the Soviets to alter their policy, Lerner was permitted to attend an international meeting in Tbilisi, USSR, in August 1975, after western scientists threatened to boycott the conference.

The seminar on Sunday was brought to order by Azbel, raising his voice in a manner that brought to mind Moses at the Red Sea: "Yehudim Sheket"—literally, "Jews be quiet" (I have the impression that those are the only two Hebrew words he knows). Together, we covered a wide range of topics. Hershel Markowitz dealt with polymer rheology as well as with linear and non-linear viscoelasticity. I dealt with contractile proteins in muscle and non-muscle cells. Azbel discussed the decoding of DNA; Levich, charge transfer reactions in

solution; Victor Brailowsky, an algorithmic approach to diagnostic and prognostic medicine; Felix Lerner, electromicroscopy of muscle phosphorylase; and Edward Trifinov some biological consequences of clustering of pyrimidine photodemers in DNA. All of the lectures were presented in English, and translated into Russian for five or six seminar members who did not understand.

Trifinov, a 39-year-old survivor of the World War II blockade of Leningrad, whose father died in a Stalin camp, teaches his own course in molecular biology attended by the children of dissident scientists, among others. His first lecture coincided with the third day of the symposium, and he was terribly excited when I presented him with my last minute purchase, a new edition of Watson's *Molecular Biology of the Gene.*

At the conclusion of our first lecture, Azbel presented Hershel Markowitz and me with commemorative pins labelled with the initials MSCP—Moscow Seminar on Collective Phenomenon. The pins, awarded to all seminar lecturers, contain two lines symbolising uncoiled DNA and a balance—which Azbel pointed out as the "scales of justice".

Each evening when the scientific seminar was concluded, we gathered around a table for a snack, usually consisting of bread, cheese and fish, and the informal seminar commenced. Next to talking science, we spent most of our time discussing the plight of the dissidents, particularly why they had applied to leave, and what scientists in other countries could do to help. The two most frequently cited reasons for leaving were antisemitism and the corruption of scientific research by politics.

According to the members of the seminar, anti-semitism has become a sanctioned policy of the Soviet Government, manifested in the systematic exclusion of Jews from the better universities such as Moscow State. Moreover, Jews are being denied access to many professions so effectively that Alexander Lerner, who before his dismissal occupied an extremely important position, told me he applied to leave because "there is no future here for my children".

As scientists, Jews find the situation in the Soviet Union intolerable because scientific research is so enmeshed in politics. Promotion, or even survival in one position, requires constant political clearance, which in turn requires scientists to advocate political positions and sign political statements that they completely disagree with or know to be patently false.

So how can other scientists help? The seminar members stressed several possibilities. First, continued pressure must be maintained on the Soviet auth-

orities to allow free emigration; second western scientists should refuse to deal with Soviet scientists known to be instrumental in having dissident colleagues fired (a partial list of names is available); third, scientists, particularly members of official delegations, should visit the seminar and other dissident scientists (such visits, in the opinion of the seminar members, are instrumental in protecting dissident scientists from harassment by the KGB).

After meeting and eating with members of the Moscow Seminar for five days, Hershel Markowitz and I came away with the impression that they are indeed dying from a professional point of view. This isolation, as pointed out by Benjamin Levich, is particularly devastating for the younger scientists, whose careers and development demand constant work and access to recent publications. (Some of the work presented to us at the seminar was carried in 1971.) But despite their dire situation, they remain committed to their cause, and hopeful that help will come from scientific colleagues in other countries.

At an impromptu banquet held on the night before our departure, Hershel Markowitz and I augmented the usual diet with a chocolate cake, the lucky result of joining one of the many lines that suddenly form on Moscow sidewalks. The 'party' was tempered for me by two things. The first was a feeling of unreality brought on by the clash between a strong sense of identification with my dissident friends on Thursday night and the knowledge that on Friday afternoon I would be able to stop by my own laboratory to check on the latest results.

The second was Azbel's closing address. Besides warning of the potential scientific demise of dissidents, he pointed out that "although most Russian scientists are resigned to restrictions on their scientific freedom, for the dissident scientists this situation is intolerable. The dissidents would rather trade their prestige and, if necessary, their careers, for freedom. In this sense all scientists who apply to leave the Soviet Union must be understood as fighters for the freedom of conscience".

● Six months after my departure from Moscow little has happened to alter the status of the seminar members. Benjamin Fain, one of the few seminar scientists still working during my visit, has been fired. Several other members, including Azbel, Levich and Viktor Brailowsky have been harassed and threatened by the KGB, in an effort to get the seminar to disband. But still the meetings continue, soliciting visits from western scientists, among them the members of official delegations.

One month ago I received a letter smuggled out of the Soviet Union from Viktor Brailowsky. He and his two children have been granted permission to leave, but as often occurs there is a catch. Irene, his wife, is still refused permission—and the family will not leave without her. In his letter he appealed for scientists to send "letters, telegrams and telephone calls (the last are helpful) to R. V. Khochlov, Rector of Moscow State University", asking that she be permitted to emigrate together with her family.

Enclosed with Brailowsky's letter was a letter from another refusnik, German A. Shapiro, an endocrinologist and a former Assistant Professor at the Institute of Biophysics in Moscow. Discharged after applying for a visa in 1972, he now works as an ambulance attendant. The official reason for denying Shapiro permission to emigrate is that he had treated "patients who might know state secrets".

Two incidents illustrate that what at times appears to be a ludicrous situation, actually involves life and death. Tanya Levich has recently suffered a heart attack. Three years ago when the Soviet Government sent her son, Yevgeny, to a prison camp in the Arctic Circle, one of the reasons given for not letting Benjamin Levich emigrate was that it would be cruel to break up the family (since Yevgeny was obviously not free to leave the country). Now, having allowed Yevgeny and his brother out, the Soviets seem intent on making sure that Benjamin and Tanya never see their sons (and grandchildren) again.

The second incident involves another letter delivered by 'special courier'. While I was in Moscow, Alexander Lerner, knowing I had training in cardiology, showed me some electrocardiograms taken on Yefim Davidovitch. Davidovitch was a much decorated World War II hero who chose to sacrifice his career in an effort to emigrate to Israel. He was, however, quite ill, and clearly had heart disease. His friends, including Lerner, were concerned that he might not survive the difficult life imposed on refusniks (his phone had been disconnected and he had been refused treatment by certain doctors and hospitals). After inspecting the cardiogram, I suggested that letters to some high Soviet health officials might be helpful in gaining his release on medical and humane grounds. I asked that a copy of his medical record be forwarded to my laboratory so that I and others could write on my return. Approximately two months after I returned, a detailed report on his medical history and physical examination arrived. Unfortunately, Yefim Davidovitch had died two weeks earlier. □

Soviet dissidents (3)

View from the Promised Land

Nechemia Meyers assesses the opportunities for
Soviet scientists arriving in Israel

Alexandr Voronel, vantage point

"AMONG the Russian immigrants are scientists on a par with the best in the US, and their coming to Israel gives this country a unique opportunity to develop many new research areas". So says Professor Alexandr Voronel, a Soviet expert in solid state physics formerly associated with the Institute of Physics at Chernogolovka, near Moscow, who joined the staff of Tel Aviv University. Voronel and his colleagues fear that this opportunity may be missed for lack of a coherent science policy in general and a plan for the absorption of these scientists in particular.

Exactly how many immigrant scientists have come here from the Soviet Union is impossible to determine, particularly because the term "scientist" covers a broader category of people in the East than it does in the West. Absorption authorities speak of 800 scientists and 400 graduate students (among the 100,000 Soviet immigrants who have arrived since 1971). Voronel thinks there are between 1,000 and 1,500, making up perhaps 15% of Israel's scientific community (as compared to about 25% of her doctors).

Those who have found employment in their professions work for the most part in universities and research centres. However, many hold temporary positions financed not by regular budgets but by special two- and three-year allocations from the Absorption Ministry and the Jewish Agency. When these allocations run out, the institutions where they are now working, which are so short of funds that they have had to fire some members of their academic staffs, will find it difficult to offer the immigrants permanent posts. In any case, future immigrants will find the universities closed to them.

This being the case, efforts are being made to channel immigrant scientists into industry. For example, the Centre for Absorption in Science announced that it was now sending 40% of its applicants to industrial firms, as compared to 10% 2½ years ago. However, as things stand, the absorptive capacity of Israel industry is also limited unless structural changes take place. For their part, the Russian immigrant scientists, or at least some of them, feel that Israel should pay heed not so much to the American experience, as some have suggested, but to the Russian one.

"When I was in the Soviet Union," Professor Voronel stated earlier this year, "I was surprised that the Americans with all their resources and techniques had no scientific advantage over the Russians in many fields. Now that I am in Israel—that is to say within the framework of Western science—I wonder why the Russians are not doing even better, because from my vantage point I can see great advantages to the organized and planned system that exists in the USSR." Voronel says that with rare exceptions, such as the Manhattan Project or the attempt to land a man on the Moon, US research is based on individual initiative and achievements. In contrast, the USSR creates scientific teams geared to achieving specific national goals.

Voronel and his colleagues fully appreciate the freedom offered to them in Israel, which they would not forego in any circumstances; but they nevertheless believe that Israel requires a less "American approach" to science policy. "The US is big enough," Voronel declares, "to achieve success, without overall planning, in a great many fields. Israel, in contrast, will achieve very little without concentrating its efforts on a few well-defined projects, and this is where immigrant scientists from the Soviet Union can be of great value. They know how to organise and apply research though, of course, they must be better acquainted with the requirements of the Israeli economy before they are in a position to make concrete suggestions."

The Diamant brothers, Lev and Emanuel, are also drawing on the experience of Russian science in their attempt to create Arshach, a science-based community in the Galilee. They hope it will eventually expand into a kind of Academ Gorodok, the large Siberian research centre near Novosibirsk where Lev Diamant studied and worked in plasma physics before coming here. In spite of the fact that both brothers found positions in Israel soon after their arrival—Emanuel Diamant as an engineer at Tel Aviv University and Dr Lev Diamant as a physicist at the Weizmann Institute—they wanted to do more than just earn a living. They wanted to lay the foundations for the absorption of hundreds or even thousands of fellow scientists from the Soviet Union in a self-supporting scientific community to include both research and development and production facilities.

Their little settlement, perched on the Galilean hills not far from the spot where Christ gave his Sermon on the Mount, is no Academ Gorodok as yet. In fact, a lack of housing limits it to a few families and a modest research and development programme, most of it based on subcontracts from established research centres in such fields as solar energy, custom-made electronics, electro-optics and lasers. Lev Diamant, who turned down US job offers, is not worried that the settlement is growing very slowly or that it is some distance from existing scientific and industrial complexes where computers, libraries and other important facilities are to be found. "In the US many scientists travel 60 miles, for example between Burlington and MIT, without thinking about it; why then," he asks, "should we Israelis make such a fuss about travelling 90 kilometers between Arshach and Haifa?"

The settlement has already established itself as an intellectual centre for immigrant scientists from the Soviet Union. The famous scientific seminars held in Moscow by Jewish scientists who had been dismissed from their posts after applying for an exit visa have been recreated at the village. They are headed by Professor Voronel, who was himself a key participant in the Moscow seminars before finally being permitted to leave for Israel last year.

Yet the purpose of these seminars, is different. "In Moscow," Voronel explains, "we were forced to concentrate on theoretical subjects because the authorities had taken away our laboratories and our instruments. Here we are discussing applied research, which we are trying, so far without too much success, to develop in Israel."

Soviet dissidents (4)

Trying to keep in touch

Yevgeny Levich describes the complex procedure involved in obtaining permits for travel abroad

WESTERN scientists welcomed the development of scientific contact with the USSR which came with détente. But enormous obstacles remain. A Soviet scientist intending to go overseas to take part in a conference or in some scientific exchange programme has to go through a complicated bureaucratic procedure, like any other Soviet citizen going abroad.

The first stage consists in obtaining a character reference (*kharakteristika*) which must be confirmed by the administration of his place of employment, by the local party organisation and his trade-union branch. The reference deals, among other things, with such matters as the applicant's participation in public activities, his moral image and his relations with the all grades of staff at his place of employment. Accompanying the reference is a detailed questionnaire covering the applicant's nationality, his party membership, details about all his former places of work and so on. The applicant is also asked to supply detailed information about his close relatives (including divorced spouse). When he has obtained the reference he is called for an interview to the Regional Committee of the Communist Party, where he is given the instructions which complete the open part of the precedure.

The main mechanism of issuing permits for foreign travel remains hidden from the eyes of the applicants. The outsized apparatus of the foreign Section of the Academy of Sciences of the USSR (General Korneev of the KGB has been head of this section for many years) or the ministries in charge of the various scientific research institutes are the bodies which deal with "travel matters". The central KGB has the last word in making decisions, which are communicated to the prospective traveller, as a rule, a day or two before his intended date of departure. There have been cases when a travel permit was taken away when the person was boarding the aeroplane.

In practice, the administration of the local institute (and especially its "first section"—the secret section which exists in every scientific institution and is connected with the KGB) plays an important part in making the decision. The deputy director of the institution, who is normally the head of the "first section", is also responsible for all international contacts. The information about the applicant which is passed on

through the closed channels has much more weight than his official reference. After the sanction of the Foreign Section has been received and confirmed by the KGB the "travel case" is transferred to the "Commission on Travel", headed for many years by the Politbureau's chief ideologue Mikhail Suslov.

The considerable efforts which are made to obtain permission to go abroad reflect the attraction that travel has for the Soviet scientist. Purely scientific considerations play the significant part here, of course, especially considering the almost complete isolation of the Soviet scientists in the recent past; but such academic interests are reinforced by financial attractions and considerations of prestige. Foreign travel is graded, like the Soviet elite's other privileges, according to value. Short trips to scientific conferences for which the scientist himself must pay are thought to be least attractive. It is much more difficult to be included in an official delegation going abroad at the state's expense. Then there is the rare possibility of going abroad for a long period of time, for example, within the framework of scientific-exchange programmes. Additional grading differentiates between travelling to the countries of Eastern Europe (not always easily obtainable) and travelling to the West.

The possibility of receiving a permit to travel abroad, and the efforts which must be undertaken to obtain it, are determined by a vague but identifiable correlation between the prestige value of the trip and the applicant's personal qualities. Being a party member, holding an official academic position, having personal connections in the administration and personal initiative are all to the applicant's credit; having relatives abroad, an unsuitable nationality, and a lack of interest in the party are not. Negative characteristics are usually critical and they automatically block off the entrance to some—if not all—ladders of privilege. On the other hand, some persons can arise to a level of the administration and party where they can by-pass the usual procedures and plan their trips more freely.

Moving up on the ladder of privileges and, in particular, gaining access to overseas contacts presents additional demands, the violation of which could mean the immediate loss of all that had been achieved. Scientific contacts between Soviet scientists and the West

Sakharov, attacked

are subject to fairly strict control. Two examples:

● Every scientist must present a detailed report, including not only details of scientific and industrial significance, but also characteristics of all the Western scientists whom he met, to the Overseas Section of the Academy of Sciences.

● Each scientist meeting with overseas colleagues at his home or at his institute must receive permission for such a meeting from the "first section" of his work-place. He must also present a detailed report about the meeting to the "first section" afterwards.

Evasion of these obligations automatically stops access to foreign contacts. On the other hand, some Soviet scientists deliberately overestimate the importance of their overseas contacts and their knowledge of scientific and industrial works in the West in order to increase their chances of a permit for their next trip.

Strict control applies not only to personal contacts, but also to scientific publications: all materials sent abroad, including letters to colleagues, must go through the special commission in every institute, which include representatives of the "first section". After being checked by the commission the materials must receive the sanction of the censorship office (the *Glavlit*). A particular form of control has appeared with the inclusion of Soviet representatives on the editorial boards of some international magazines, providing an opportunity to prevent publication of articles in foreign magazines.

Those who can travel abroad because of their position naturally enjoy significant advantages in the struggle for power which goes on in the upper layers of the Soviet academic community. But whereas scientific life inside the USSR is controlled to a significant extent by the representatives of the Soviet scientific elite, in matters connected with foreign contacts the

critical influence is concentrated in the hands of the party apparatus and the KGB. The selectively chosen representatives of the scientific elite have, however, merged with the administrative and party elite: those who have signed letters attacking Sakharov, those who have dismissed Jewish scientists wanting to emigrate from the USSR, and later signed false secrecy certificates of these scientists, are themselves scientists. Their actions are dictated not by their scientific but by their administrative interests, by their proximity with the party oligarchy and their desire to use this in their struggle for rank and power. They are the ones who appear most often at international conferences; they are the ones who gain most from the "scientific détente". The strengthening of scientific contacts

with the West, as long as they develop in a way suitable for the Soviet authorities, increases the influence of the most rigid elements of the Soviet establishment and provides them with additional levers to influence scientific life in the Soviet Union.

Soviet citizens differ from one another in everything, just as citizens of any Western country do. In accordance with the spirit of the "third basket" of the Helsinki Declaration, contacts ought to be developed on the individual level and not on the level of the delegations selected by the authorities. The organisation committees of international conferences should reserve the right to invite to conferences Soviet scientists who are prominent in their field, and should make their attendance a condition for the attendance of the

official Soviet delegation. The participation of Western scientists in any scientific exchange programmes must be conditional on the Western side being able to choose at least some of the members of the Soviet delegation and being able to have free contacts with any scientists in the USSR whom they would like to meet. Soviet scientists must also retain the right to send their articles to foreign magazines through members of the editorial board as well as through the Soviet regional editor.

Measures such as these would not cause a halt to scientific contact with the West. The needs of the state, and of the members of the elite, ensure that. And they represent something more than mere declarations of support or solidarity. ☐

COMECON

WITH growing industrialisation, fuel and power supplies are a matter of increasing importance to the Comecon block, particularly as the new policy of economic integration begins to take effect, and considerable reliance has come to be placed on oil, gas, and electricity delivered from the Soviet Union by pipeline and cable. But despite official Soviet statements that fuel and power export commitments would remain unaffected by the new drive for economies at home, it seems that there will after all be an export cutback. During a recent Miners' Day rally in northern Bohemia it became apparent that deliveries of Soviet oil to Czechoslovakia over the next five years would "fall short" of original estimates. Accordingly, the Czechoslovak Government has concluded that "we shall be unable to maintain the growth rate of past years".

There are other problems too. An article in the Slovak *Pravda* notes that in spite of the additional 4,000 MW or so of new generating capacity planned for the next five years (which should include two atomic reactors at Jaslovske Bohunice, providing some 35% of the total new capacity for Czechoslovakia), the generating system will still have "minimal reserves" and will be constantly stretched.

Nuclear power is a matter of pressing importance to Comecon, and, not surprisingly, there is considerable international cooperation. Joint research into the construction of the necessary equipment, which has resulted in the development of new types of generator, is carried out by Interatomenergo and Interatomininstrument. The latter organisation

is the only Comecon enterprise to have its own autonomous accounting system and operating capital of convertible currencies. Atomic power stations are being constructed (with Soviet aid and expertise) throughout the Comecon block, notably at Lake Zarnowiec in Poland, and Paks in Hungary. Ultimately, they should all

be connected with a 750 kV grid, the first line of which, from Ukraine to Hungary (with a later extension planned to Yugoslavia), should be commissioned in 1978. By 1990, nuclear power stations should meet one-quarter of the forecast electricity demand of the Comecon block.

In the meantime, to fill the energy gap, conventional fossil fuels are in ever increasing demand, and intensive work is being carried out both to modernise existing coal mines and to develop new ones. One such project, described recently by the Prague television service, bears a touch of inadvertent humour. A new open-cast coal mine, which will provide fuel for a power station in northern Bohemia, is, in line with the Socialist custom of naming important enterprises after

revolutionary heroes, to be called after Maksim Gor'kii. One of Gor'kii's most famous works is entitled *'From the Lower Depths'*.

● The drought which this year has affected all the European members of Comecon together with certain western parts of the Soviet Union (though not the Moscow region, where too much rather than too little rain has been the problem), has forced the authorities to place a new emphasis on the utilisation of water resources. Some research had, indeed, already begun with the mapping last winter and spring of Carpathian water-resources. That survey did not, however, extend to the eastern regions of the Carpathians (Ukrainian SSR), where over-zealous tree-felling is apparently resulting in erosion and consequent "destruction" of the water table. Precipitation in the Carpathians is of vital importance to the water supplies of Poland, Czechoslovakia, Romania, Hungary and Ukraine.

Several local water economy schemes are now being implemented. These include anti-flood measures on the Tisza, Mura and Raba in Hungary, a dam on the Cirocha in Slovakia, a special turbine-type aerator for the purification of polluted river water (developed at the Purification Equipment Institute in Sofia) and a reservoir on the Odra near Mietkow in Poland. Although, like the Carpathian survey, many of these projects were already envisaged or under way before the drought became a pressing problem, the considerable media coverage they have received indicates that water supply has become an issue of grave importance.

IN BRIEF

Synthetic fuel block

A controversial plan to pump billions of dollars of federal funds into the commercial production of synthetic fuels in the United States was unexpectedly killed off in the House of Representatives last week. By the narrow margin of 193 votes to 192, the House blocked further consideration of a Bill to provide up to $4,000 million for the construction of large-scale plants to produce oil from shale, and oil and gas from coal. The vote means that there is now no chance that Congress will pass the legislation before it breaks up for the November elections. The Bill was a major plank in the Ford Administration's long-term energy strategy, which calls for the production of large quantities of synthetic fuels by the mid-1990s to replace dwindling domestic supplies of oil and gas. It was defeated by an odd assortment of bedfellows ranging from environmentalists fearing the pollution threat from conversion plants, to right-wingers opposing federal subsidies for industry.

Energy get-together?

Democratic Presidential candidate Jimmy Carter last week offered a plan to consolidate an assortment of government agencies in the United States into a single Department of Energy. Stating that "our country still has no energy policy" three years after the 1973 oil embargo, Carter said that the new department would include the Energy Research and Development Administration, the Federal Energy Administration, parts of the departments of Commerce and Interior, together with the Federal Power Commission. The plan would have a tough time getting through Congress if Carter is ever in a position to propose it formally, however. Former President Nixon twice suggested the setting up of a Cabinet-level department of energy and natural resources, but the reorganisation was never approved by Congress because it would have cut across the jurisdictions of many Congressional committees, which now roughly match those of existing departments and agencies.

Bangladesh council

The Government of Bangladesh has constituted a National Council for Science and Technology to plan the country's scientific and and technological programme and activities. The high powered council is chaired by the President of Bangladesh, and one of the two vice-chairman is an eminent scientist who is also the Science Adviser to the President, Professor M. Innas Ali.

The council has 19 other members who are *ex-officio* chairmen of research councils, secretaries of some ministries, Vice-Chancellors of two technological universities and two reputable Bangladesh scientists or technologists nominated by the President. Professor Ali himself has a distinguished career in scientific research, education and administration. He holds a Master's degree in electric engineering from the University of New York, a doctorate in nuclear physics from the University of London; and is a former Vice-Chancellor of Chittagong University.

SECRECY, in science as in politics, is a delicate and difficult subject. There is much concern when the details of Cabinet deliberation are prematurely revealed, yet at the same time there is a strong campaign for the relaxation and rationalisation of the Official Secrets Act. It is difficult to strike a happy medium. The results of scientific research concerned with military problems or commercial activity may legitimately be kept secret for a time, but it often seems that publication of much of this work is delayed unnecessarily. Some results which might have a wide application never see the light of day, even when the defence of the country is no longer at risk, and when no benefits would immediately accrue to a company's commercial rivals.

The reputation of a scientist depends largely on the quality and quantity of his published work. If he is unable to publish, he is likely to remain unknown except among his immediate colleagues. It is therefore important to the individual, as well as to the scientific community, that as few restrictions as possible be placed upon the publication of the results of any kind of research. High salaries, or even the award of honours and decorations to otherwise unknown scientists may be poor recompense for the denial of proper recognition within the scientific community.

When the reorganisation of

government-supported research attributed to Lord Rothschild was being discussed, there was some concern that it might have a harmful effect on the dissemination of scientific know-

---

ledge. It was feared that the executive government departments, to whom so much of the research funds was to be transferred—so that they, as "customers", could place "contracts" with research councils or other laboratories—might be reluctant to allow the scientists who did the work to publish their results in the accepted scientific journals. These particular

fears appear to have been unfounded. Some senior ministry officials have suggested that since they paid for the research, they should have the right to decide what should and should not be published. But it is to the credit of Chief Scientists that they normally insist that those engaged in research should be free to publish as they wish. Indeed, in some cases contracts have included the proviso that results should be made available to the customer first, and there seem to have been few cases where final publication has been seriously delayed.

And yet the new system appears to have reduced substantially the amount of material being published by some of the laboratories now largely engaged in contract research. The reason would seem to lie in the nature of the contracts themselves. Few contractors seem to have followed the example of the Ministry of Agriculture, Fisheries and Food, whose contracts have usually been for very large sums, and have covered substantial fields of study, so as to allow room for manoeuvre and originality. Too many contracts have been small and circumscribed by limited objectives, presenting few opportunities for research workers to make significant advances. There has consequently been little worth publishing. And in that situation, it does not matter whether or not the workers are pledged to secrecy.

Complementary mispairs

from E. G. Richards

THE fidelity of DNA replication is a matter of crucial importance : too low, and life as we know it is impossible; too high and there is no evolution for us to ponder the matter. The observed frequency of mutations and replication errors must depend on several factors, including the nature of the error, the chemistry of the replication machinery and the fundamental chemical properties of the bases in DNA themselves.

An interesting theory has been propounded by Topal and Fresco (*Nature*, **263**, 285; 1976) to account quantitatively for the observed frequencies of a certain class of mutation—point mutations which entail the substitution of one base pair for another in the DNA.

Such point mutations can be of two sorts: transversions in which an A–T or G–C base pair is substituted for its opposite number, namely a G–C or A–T pair respectively; and transitions in which the pair is reversed between the two DNA strands so that an A–T pair becomes T–A or G–C becomes C–G.

As is often stated, the Watson–Crick base pairs, A–T and G–C, are each complementary. Among other things, this implies that both sorts of base pair are geometrically similar and can substitute for each other in the regular DNA helix. The crucial observation, based on model bulding, of Topal and Fresco is that there are other sorts of base pair which are geometrically similar to the normal Watson–Crick pairs. These they have termed complementary mispairs, and they are formed from bases which are in thermodynamically rare forms such as the enol or imino forms or in the *syn* rather than the normal *anti*-configuration (obtained by rotating the base through 180° about its glycosidic bond).

In the replication process, each base in turn selects, with the aid of the enzymes involved, a complementary partner which is incorporated into the growing chain. If on rare occasions a base, instead of selecting its normal partner to form a normal Watson–Crick base pair, selected another partner to form a complementary mispair, an error or mutation would be born. Topal and Fresco find that all possible transversion and transition mutations could come about in this way.

Considerable credence is lent to this idea by the report that base oppositions corresponding to each of the required complementary mispairs have been demonstrated experimentally to take up intrahelical conformations in long double stranded polynucleotides dominated by normal Watson–Crick base pairs, whereas other base pairs which are not complementary and are not required take up extrahelical conformations instead.

So far one might suppose that the frequency with which a transversion or transition occurred would be determined mainly by the proportions with which the different nucleotides exist in their rarer tautomeric or isomeric forms. These proportions are determined by the thermodynamic properties of the bases and have in fact been measured. The results suggest that the enol or amino forms would occur at a frequency of 1 in 10^4–10^5 and the *syn* form at 1 in 10–20. These frequencies are however far higher than those at which point mutations are observed to occur—1 in 10^9–10^{12} base pairs replicated.

In circumventing this difficulty, Topal and Fresco note that there is good experimental evidence that replication takes place in two stages. In stage one, the replicative machinery holds the template base in position and presents a hole into which only a complementary base may fit to be joined to the growing strand. At this stage a mispair may be formed with the frequencies noted above. In the second stage a checking mechanism is brought into play which ascertains if the newly formed pair has standard geometry. If not it is excised. Topal and Fresco propose that before the check is completed, thermodynamic equilibrium is re-established and the tautomers revert to the keto or amino form with a corresponding disruption of the geometry (because of stacking interactions it is likely that the *syn-anti* equilibrium is frozen). At frequencies determined by the same thermodynamic considerations, however, a small proportion of mispairs will remain mispaired and not be detected. Thus the proportion of mispairs that are both formed and survive the checking step will be approximately the square of the proportions mentioned above. Topal and Fresco have worked out in detail from their proposed mispairs and the relevant thermodynamic data the frequencies at which they would expect the various sorts of point mutation to occur. They find a remarkable agreement with data obtained from a study of the frequency of spontaneous mutations in the tryptophan synthetase A gene of *Escherichia coli*.

One interesting feature in the proposed base mispairing schemes is that transitions arise only from purine–pyrimidine mispairs and transversions only from purine–purine mispairs. It is therefore of interest and wholly consistent with Topal and Fresco's hypothesis that the base analogue 5-BrU has the specific effect of enhancing the frequency of transitions. 5-BrU also has a much greater tendency to enolise than its natural counterpart T. Similarly they can explain the specific effect of

2-AP in inducing trasversions. They go on to comment that chemical mutagens (many of which are carcinogenic) may act by disturbing the tautomeric or isomeric equilibria of bases with which they interact.

This hypothesis is certainly elegant but as the authors point out, further experiments are required to assure its validity. Be this as it may, if it is valid, similar effects may well occur in other situations in which complementary base pairing is invoked. In particular it may occur in transcription and in mRNA interactions with tRNA during translation on the ribosome. Such matters are the subject of a second paper by Topal and Fresco (*Nature*, **263**, 289; 1976).

Any discussion of codon–anticodon interactions in translation must be dominated by Crick's wobble hypothesis. Topal and Fresco devote part of their paper to a discussion of what base pairs could and could not occur in the third codon wobble position. One suggestion they come up with is that in the wobble pair A–I, the A residue on the codon may be in the

syn configuration rather than the *anti* as proposed by Crick. This would give a glycosidic bond separation close to the standard 10.9 Å instead of the longer value of 12.8 Å.

Whatever the precise nature of the wobble pairs may be, mispairing would lead to errors in amino acid incorporation. The *in vivo* rate of such errors is as high as 1 in 10^4. This figure, Topal and Fresco surmise, results from mispairing in the transcription process as well as in all three positions in the codon–anticodon interaction. The calculation of the value expected on the basis of mispairing schemes and the tautomeric equilibrium constants is complicated by the degeneracy of the code, but ignoring this difficulty, Topal and Fresco arrive at a value of 1 in 4×10^4 for the overall error rate. Presumably there is no checking process analogous to that in replication. This may be because the errors can arise at two distinct stages—transcription and translation—at roughly the same frequency so that the economics of the cell would render it unprofitable to check errors at one stage only. ☐

climates to observe the shape of a single flagellum, even though its diameter is only 20 nm. The advantages of this over electron microscopy are that distortions and environmental changes induced by specimen preparation can be avoided, and phase transitions observed directly while the medium is changed. Such transitions include a change from left- to right-handed helices on reducing the pH.

Kamiya and Asakura describe how this change occurs in reconstituted *Salmonella* flagella. The change is rapid and reversible, and can be seen to start at one end of a flagellum and propagate down its length. As this happens, the transformed region appears to rotate rapidly round the remainder, which in their experiments was tethered to the slide. Similar effects can be induced by hydrodynamic forces, and Hotani's ciné film of this sort of motion has recently been gripping scientific audiences around the world. The experiments show clearly that the transformation is due only to a reorientation of the subunits, in a process akin to that postulated by C. R. Calladine (*Nature*, **255**, 121; 1975) to explain the different static waveforms that can occur.

Hotani's companion paper concentrates on the static appearance of flagella of mixed type, in which polymerisation is started with one monomer mixture and finished with another. As well as measuring accurately the parameters of the helices, Hotani measured the "block angle" between the axes of helices at the point of changeover. There seems to be no kink in the structure, but the transition from one form of packing to another causes the new helix to coil about a different axis. This is particularly marked when the handedness reverses; the block angle can then be as small as 94°. The most interesting feature of Hotani's results is that nearly all the data fit a simple equation relating the block angle to the pitch angles of the two helices concerned. This equation demands a condition which also underlies Calladine's prediction of helical polymorphs.

This prediction followed the observation that a flagellum is made up of longitudinal rows of subunits which generally make a small angle with the rod axis. The large scale helices adopted are consistent with some of these rows running always along the inside of the helix, while other rows (of slightly greater length per turn of helix) run always along the outside. Calladine showed how "short" rows could arise by rearrangement of the connections between subunits, and he argued on purely mechanical grounds that such rows should cluster on one side of the rod. A transition between polymorphs would then involve a

Structure of bacterial flagella

from Michael Spencer

BACTERIAL flagella fascinate biologists, molecular and otherwise, for a number of reasons. They are built up from identical subunits; they are helical (look what that did for Watson and Crick); and they constitute a largely unsolved problem in motility. It seemed a couple of years ago that the important question of whether they rotate bodily or merely execute helical waves had been settled in favour of the former idea; certain lines of indirect evidence convinced many scientists that there must be some kind of molecular motor, complete with bearings, at the base of each flagellum. However, direct evidence for the functioning of such a device has been lacking, and a minority remains sceptical. The case for the new doctrine was summarised in a persuasive article by Howard C. Berg entitled *How Bacteria Swim* (*Sci. Amer.*, 36, August, 1975).

Meanwhile a number of workers have refrained from committing themselves firmly to any hypothesis, and have continued to publish new structural data. The most prolific of these has been Sho Asakura of Nagoya University, who has specialised in the

repolymerisation of flagella *in vitro*. By mixing seeds and monomers from various mutants, a number of flagellar forms can be produced which vary in the pitch, amplitude and handedness of the large-scale helix into which the basic rod structure is coiled. Others have used optical diffraction of micrographs to study the detailed packing of subunits (for example, Kondoh and Yanagida, *J. molec. Biol.*, **96**, 641; 1975). It is unfortunate that almost every worker in the field has invented a new terminology to describe the helices, and evocative but imprecise terms such as "curly" and "semi-coiled" have served to keep the non-specialist confused.

The two most recent publications in this field are by Hotani now at Kyoto University, and by Kamiya and Asakura (*J. molec. Biol.*, **106**, 149 and 165; 1976). Both papers describe the use of dark-field light microscopy, which has recently undergone quite a renaissance. Thirty years ago it was used by Pijper to observe flagellar bundles in motion, using sunlight on the roof of his South African laboratory. By using a high-intensity lamp it is now possible for workers in shadier

change in the number of "short" rows, but not in the side on which they clustered. Hotani's results are consistent with this argument.

What is intriguing is that the kind of structure described is also required by the basic "non-rotary" hypothesis for generation of helical waves, an idea with a lineage going back to 1883. On this hypothesis the packing pattern would be induced by some mechanism at the base to propagate round the rod, giving rise to apparent rotation. Although Hotani follows Kamiya and Asakura in eschewing speculation, their results taken together suggest that there could yet be some life in the old idea. □

The folded chain's last stand?

from Paul Calvert

IN the past two years low angle neutron scattering studies on amorphous polymers have shown that the chain dimensions in both the liquid and glassy states are equal to the random coil dimensions seen in ideal solution. This scotched the idea that there are ordered regions in amorphous polymers but has left the puzzle of how to pack chains to high density yet retain the random coil (Kirste *et al., Polymer*, **16**, 120, 1975; Cotton *et al., Macromolecules*, **7**, 763, 1974; Wignall *et al., Eur. Polymer J.*, **10**, 861, 1974).

Results of similar experiments on crystalline polymers are now being published and very surprisingly show that the chain is still in a random coil. This one fact contradicts much of our current understanding of polymer crystallisation.

The small angle neutron scattering experiment is similar to small angle X-ray scattering except that the contrast arises from the very different scattering powers of perdeuterated and protonated polymer rather than from density differences. Usually a few percent of normal polymer is mixed into a matrix of wholly deuterated chains. The strong incoherent scattering from the protonated chains is measured as a function of angle and allows their radius of gyration and molecular weight to be determined. For amorphous polymers the radius of gyration was found to be equal to the ideal solution value. The apparatus necessary is a nuclear reactor with a thermal neutron beam and a diffractometer. Experiments have been done at Harwell but the beam intensity there is low and much more can be done on the purpose-built research reactors at Grenoble and Jülich

Was the early Solar System windswept?

from David W. Hughes

IF the nebula that formed the Solar System had the same elemental composition as the Sun, the condensates, that is the planets, asteroids and comets which make up our present Solar System, represent only about 5% (by mass) of the original nebula. The remaining 95% has been lost in the intervening time between planetary formation and the present. Most modern cosmogonical theories use the solar wind to sweep the newborn Solar System free of this "left over" nebula which is made up mainly of volatile elements such as hydrogen and helium. This solar wind is a cloud of particles (mainly protons) which are streaming away from the Sun. At the present time the average cloud density near the Earth is 5 protons cm^{-3} and the particles stream past at a speed of about 450 km s^{-1}. In the T Tauri stage of the Sun's evolution this wind was blowing at about the same speed but was much denser, the Sun losing mass at a rate which could have been as high as 10^{19} g s^{-1}. This T Tauri stage lasted around 50 million years during which time the Sun's radius decreased from nearly that of the radius of Mercury's orbit to its present 7×10^5 km and the Sun lost a considerable percentage of its mass. The Sun was also a variable, surrounded by a thick, highly active chromosphere. Gravitational collapse was giving way to thermonuclear hydrogen burning as the main energy source

M. J. Handbury and I. P. Williams (Queen Mary College, University of London) question the wind-sweeping

hypothesis in a recent paper in *The Observatory* (**96**, 140; 1976). Assuming that the solar gaseous nebula is in equilibrium about the Sun before the onset of the wind the authors then calculate the rate of momentum transfer between a continuous, spherically-symmetric wind and the nebula. Three forces are acting on the nebula, gravity, "centrifugal force" due to its rotation and the solar wind force due to its rotation and the solar wind force due to momentum transfer. As angular momentum is conserved a formula can be easily obtained for the new equilibrium distance between the nebula and the Sun. Handbury and Williams find that for all reasonable values of the parameters the nebula does not get pushed out to infinity by the T Tauri wind but simply increases in radius.

Now if energy transfer and not momentum transfer is the actual mechanism the total nebular energy could become positive and the nebula would disperse. But this would require the kinetic energy of the wind to be converted into thermal energy in the nebula and then back again into kinetic energy as the nebula moves away. Also loss due to radiation, evaporation or fast moving particles and other mechanisms has to be negligible.

So the authors conclude that the solar wind cannot be the broom which swept from the Solar System those elements that did not condense to form the planets and that cosmogonists must look for another process.

(see Schmatz *et al., J. appl. Cryst.*, **7**, 96, 1974; for a general description of small angle neutron scattering).

The first experiments on crystalline material showed that the scattering was dominated by scattering from the matrix attributed to submicron voids. This effect could be eliminated by using deuterated polymer in protonated matrix rather than *vice versa* as the scattering lengths of the protons and carbons almost cancel. It then became clear that segregation was taking place so that the deuterated polymer was clustering in the crystals as the measured molecular weights were many times the true value (Schelten *et al., Polymer*, **15**, 682, 1974: *Colloid and Polymer Sci.*, **252**, 749, 1974). This arises because deuterated polyethylene melts at about 6 °C below the protonated polymer.

The next set of results to be pub-

lished were those of Sadler and Keller (*Polymer*, **17**, 37; 1976). They measured solution grown single crystals in the range of scattering angle appropriate to the interchain spacing in the crystal rather than the chain as a whole. They showed that their results can be explained in terms of an adjacent re-entry model but could not really eliminate alternative models. These experiments may have been affected by clustering which could invalidate the results.

During this summer results on melt crystallised polymers have been reported at several conferences by Ballard, Wignall and Longman from ICI at Runcorn using the Jülich diffractometer (to be published in *Polymer*). They tried to eliminate clustering by using a branched chain protonated polyethylene in conjunction with a linear deuterated polymer so that the crystallisation temperatures

matched. They found that even with such matching they could not eliminate segregation except in samples crystallised by quenching. Neutron scattering measurements were made on these samples down to low enough angles to observe the radius of gyration of the whole chains. For quenched samples they found a value of ratio of radius of gyration to the square root of molecular weight $\langle S^2 \rangle_w^{\frac{1}{2}}/M_w^{\frac{1}{2}} = 0.46 \pm 0.05$, the same as for molten polymer and ideal (θ) solution. Over the molecular weight range from 40×10^3–400×10^3 it is not possible to tell whether there is a change in the ratio. At concentrations of deuterated polymer less than 10% the quenched samples gave correct molecular weight values showing that no clustering occurs. Slowly crystallised samples give a molecular weight value several times too high due to clustering.

The significance of these results is that they undermine the folded chain theory of crystallisation in which each polymer chain crystallises in a 'jumping jack' configuration, repeatedly traversing the crystal thickness of about 100 atoms (a stem) then folding back on itself. The chain will thus have the shape of a thin sheet. This model is supported by a large amount of indirect evidence on the morphology and properties of single crystals grown from solution and by the Lauritzen–Hoffman theory of crystal growth which correctly predicts the crystal growth rates from melt and solution on the basis of adjacent re-entry folding.

One direct experiment is that of Bank and Krimm (*J. Polymer Sci.*, **A-2, 7,** 1785; 1969) who studied the infrared spectra of mixed perdeuterated and normal polyethylene and showed that even at low concentrations a deuterated stem is likely to be adjacent to other deuterated stems so that the chain must fold back on itself. The Sadler and Keller neutron experiments are equivalent to this. Mandelkern and coworkers (*Macromolecules*, **4,** 672; 1971; reply, *ibid,* **5,** 209; 1972) have raised the question of segregation in the Bank and Krimm experiments but could not really prove it. The new neutron experiments seem to have verified Mandelkern's idea and invalidated the infrared experiments. The main alternative model to adjacent re-entry folding is the 'telephone switchboard' or non-adjacent re-entry proposed by Flory but a few months ago the majority of polymer scientists accepted adjacent re-entry as the norm.

Ballard and coworkers discuss their results in terms of two models. The first, assuming the chain is in a random coil configuration, gives a good fit to both the radius of gyration and the shape of the scattering function. If adjacent re-entry folding is assumed, a fit can be obtained if the chain folds a

specific number of times then moves to a new crystal, but the constraints on the number and length of folds are such that it becomes difficult to explain the molecular weight dependence of the data. Thus the most satisfactory approach is to assume that the chain crystallises with no gross distortion of the random coil which exists in the melt, though local changes must occur. A search for other models which fit the data is being made.

These results only apply to quenched samples as the clustering disqualifies results on slowly cooled and solution crystallised samples. Defenders of chain folding can thus say that it will still apply to crystallisation nearer to equilibrium. This is unsatisfactory so long as there is no prediction as to where 'near equilibrium' ends. One major omission of theories to date is that there has been no comprehensive attempt to treat the dynamics of the chain as it attaches to the crystal. If crystallisation is slow the chain should have plenty of time to relax its shape

to a 'jumping jack' as it is attached but when the crystals are growing rapidly they may well just entrap chains with little relaxation from the random coil. At the moment there is no basis for saying where the boundary between these two regimes lies. Chain folding theories assume that the first case applies over most of the normal range, my personal opinion is that the second case may be the rule, possibly even in solution crystallisation.

In the next year we may expect more neutron results on other systems. Ideally a polymer may be found where the labelled and unlabelled chains do not segregate significantly during slow crystallisation but since the chain motions involved in segregation and chain folding must be related we may reach an impasse. The adjacent re-entry chain folding model has received a nasty blow. If it does not survive as the description of melt crystallisation much of our understanding of polymer structure and properties will have to be reassessed. □

Radioastronomy and cosmology

from M. S. Longair

The cosmological problem as it presents itself to the radio astronomer was the subject of IAU Symposium No 74, Radio Astronomy and Cosmology, which was held at the Cavendish Laboratory, Cambridge on August 16–20, 1976.

THE standard textbooks on cosmology describe how the density, deceleration and geometry of the Universe may be determined from observations of the most distant galaxies. The remarkable fact that even the brightest extragalactic radio sources are at very great distances means that in principle they can be used in all the classical cosmological tests. In practice radio sources tell us rather little directly about these properties of the Universe because the overall properties of the radio source population evolve rapidly with cosmological epoch. Radio sources are associated with the most violently active systems— the nuclei of massive galaxies and quasars—and in general terms the distribution of radio sources traces how this violent activity has changed with cosmic time. All the evidence suggests that the Universe went through a period of violent activity when it was about one-tenth of its present age. Thus the contribution of discrete radio sources to cosmological problems is directed much more towards physical

aspects of the evolution of the Universe than towards the geometrical questions of classical cosmology.

The emphasis of the symposium was on the ways in which observations of discrete radio sources provide information of cosmological relevance. In interpreting the data, attention was focused on standard evolutionary world models.

The overwhelming impression was of the wealth of high quality observational data which has become available in recent years at radio and optical wavelengths. The radio observations span a range of 10^4 in sensitivity and the associated optical objects span a range in redshifts of at least 0 to 3.53. The radio surveys have been directly responsible for the discovery of large numbers of very large redshift quasars.

All such cosmological studies are ultimately based on surveys of radio sources and very large samples of sources are now available at frequencies of 0.408, 1.4, 2.7 and 5 GHz. Perhaps the simplest of all cosmological tests at radio wavelengths is the counts of radio sources which are shown in Fig 1 in differential form. The number of sources ΔN in the flux density interval ΔS is shown normalised to an arbitrary Euclidean count $\Delta N_0 \propto S^{-5/2} \Delta S$. A major advance has been the great increase in the numbers of sources counted at flux densities $S \leqslant 1$ Jy at all frequencies. The be-

haviour of the counts at 0.408, 1.4 and 2.7 GHz is similar, showing three distinct regions: at high flux densities, $S>3$ Jy, the observed numbers of sources increase relative to the Euclidean prediction with decreasing flux density; at intermediate flux densities, $0.1<S<1$ Jy, the numbers follow closely the Euclidean prediction; at the lowest flux densities, $S<0.1$ Jy, the numbers of sources converge relative to the Euclidean prediction. It has been known for many years that this behaviour contradicts the result expected for a uniform spatial distribution of sources which is that the counts should be a monotonically decreasing function of decreasing flux density and is evidence that the properties of the radio source population have evolved with cosmological epoch. As the frequency of observation increases, the "maximum" in the normalised differential counts broadens appreciably due to the presence of a larger proportion of sources with flat radio spectra. At 5 GHz this broadening is so marked that the counts follow closely the Eucliden prediction over a wide range of flux densities. In view of the small difference in frequency between 2.7 and 5 GHz, such a difference is remarkable and suggests that a new class of radio source with flat radio spectra appear at flux densities $S_5 < 0.1$ Jy. Several lines of evidence suggest that this new class may be weak radio galaxies.

In the past there have been suggestions that there are anisotropies in the distribution of sources over the sky. The large surveys of sources made by observers at Bologna, Cambridge, Molonglo, NRAO and Parkes have now been analysed using the powerful technique of power spectrum analysis and no evidence for anisotropies has been found. The Westerbork observers reported the results of many surveys made in the flux density range $S_{1.4}<0.1$ Jy where the source counts converge and no evidence of anisotropies was found. A few claims of anisotropies were made—for example, differences in the total numbers of sources detected in different sections of the Molonglo and NRAO surveys which are significant at about the 1% level. These results must however be compared with the large body of data which reveals no significant evidence of anisotropy. A. S. Webster (Institute of Astronomy, Cambridge) pointed out that this provides the best evidence for isotropy of the distribution of discrete objects in the Universe on scales ~ 1 Gpc.

The angular diameter–redshift relation is an attractive cosmological test because all the standard world models predict a minimum in the angular size of a standard rod with increasing redshift. Since radio sources extend to large redshifts, many observers have searched for such a minimum using the physical size of radio sources as a standard rod. R. C. Roeder (David Dunlap Observatory, Toronto) reminded observers that this result is only true if the matter distribution in the Universe is uniform; in completely inhomogeneous models, the minimum disappears. Observations of the relation for radio galaxies and quasars with redshifts up to 2.8 were reported by groups from Cambridge, NRAO and Westerbork. All that could be said at present was that the angular size distribution of quasars observed at large redshifts appears to agree with what is predicted from the known physical size distribution at small redshifts although the statistics are still small.

A slightly different result is found for the related test, the angular diameter—flux density relation. R. D. Ekers (Kapteyn Laboratory, Groningen) extended the earlier work of G. Swarup and his colleagues (Radio Astronomy Centre, Ootacamund). The median angular size of complete samples of radio sources decreases with decreasing flux density until the very lowest flux densities, $S \lesssim 0.1$ Jy, at which the median attains a roughly constant value. It is not yet known if this is a minimum or an asymptote. Calculations by V. Kapahi (Tata Institute, Bombay and Groningen) showed that even the decrease in the median angular size with decreasing flux density disagrees with the postulate that the physical sizes of radio sources are independent of redshift. His results suggest that the median physical size must be smaller at large redshifts, roughly by a factor $(1+z)^x$ where $x \approx$ 1 to 1.5. This result does not necessarily contradict the direct observations of the angular diameter–redshift relation for quasars—Kapahi's result refers to all radio sources, the other to quasars alone.

Optical identification of radio sources has proved to be one of the most successful techniques for finding very distant galaxies and quasars. R. Fanti (Radio Astronomy Laboratory, Bologna) and C. Perola (Institute of Physics, Milan) showed that for weak radio galaxies there is a correlation between their radio and optical luminosities but for powerful radio galaxies, as has been known for many years, the dispersion in absolute optical magnitudes is small and is independent of radio luminosity. This means that the galaxies associated with powerful radio sources may be used in the optical redshift–magnitude relation. H. E. Smith (Physics Department, La Jolla) showed that in the past few years this approach has led to the discovery of eight radio galaxies with measured redshifts in the range 0.467 to 0.752
Fig. 1 The differential counts of radio sources at 0.408, 1.4, 2.7 and 5 GHz. The hatched areas are counts inferred from analyses of "confusion" surveys, that is, surveys in which the surface density of sources approaches one per beam area of the radio telescope. The ordinate scale is arbitrary.

and to the possibility of extending the redshift–magnitude relation for galaxies to significantly larger redshifts than before. He was not yet prepared to derive a value for the deceleration parameter from these data. For the quasars, J. N. Bahcall and E. L. Turner (Institute of Advanced Studies, Princeton) showed that despite the enormous scatter, their redshift–magnitude relation is consistent with the predictions of standard world models.

Given this increase in data, what can now be said about the evolution of the radio source population with cosmological epoch? M. Schmidt (California Institute of Technology) showed that for all available complete low frequency samples of quasars and radio quiet quasars the V/V_{max} test gives consistently values ≈ 0.65 as opposed to the value of 0.5 expected for a uniform distribution. The implication is that the quasars are found preferentially towards the limits of their observable volumes implying a strong evolutionary effect. One intriguing new result, as yet based on rather small statistics, is that the test gives the value 0.5 for flat spectrum quasars selected at high frequencies. If substantiated by improved statistics, this result will be difficult to reconcile with a simple evolutionary scheme because these quasars span a similar redshift range to those found in the low frequency surveys.

The counts of radio sources provide further constraints upon admissible evolutionary models. J. V. Wall (MRAO, Cambridge) showed that the improved statistics of the source counts make it much more difficult to find satisfactory models of the source distribution. All models require the strong evolution of only the most powerful classes of radio sources with cosmo-

logical epoch but it is not yet clear whether an abrupt cut-off to the distribution at large redshifts is necessary. Some of these questions may be answered by deep optical identification surveys of faint radio sources. The greatly increased data base provides new stimulus to the construction of models for the evolution of the radio source population.

There remain all the physical questions of the origin and evolution of radio sources and quasars. Many new facts emerged during the symposium: J. G. Bolton (CSIRO, Parkes) showed how three types of optical quasar could be distinguished on the basis of distinctive radio properties; A. Boksenberg (University College, London) showed the wealth of information contained in high resolution absorption line spectra of large redshift quasars and suggested the lines could be associated with intervening galaxies, a view opposed by E. M. Burbidge and H. E. Smith (Physics Department, La Jolla) who gave reasons for believing them to be intrinsic to the quasars; D. E. Osterbrock (Lick Observatory) described how detailed optical spectral studies of samples of radio galaxies enabled the properties of the emitting regions to be related to those found in other types of active galaxy.

The fundamental problems of understanding the origin and evolution of the radio source population and its significance for the origin and evolution of galaxies are far from being solved. It was clear from the symposium, however, that the impact of radioastronomy upon all aspects of cosmology is enormous. Detailed coordinated programmes of observation at radio and optical wavelengths of all types of radio source are now under way and this fruitful cross-fertilisation is one of the most encouraging prospects for the future of observational cosmology.

Infectivity marker for hepatitis

from Arie J. Zuckerman

INFECTION with hepatitis B virus is associated with the appearance in the serum of hepatitis B surface antigen (originally referred to as Australia antigen) and its homologous antibody. A second antigen, located in the core of the 42–45mm double-shelled spheroidal Dane particle, is intimately associated with the infection and gives rise to the core antibody. These markers have proved extremely valuable in unravelling the epidemiology of hepatitis B

and establishing the global dissemination and importance of this infection (see *Nature,* **247,** 2; 1974), have made possible the routine screening of blood donors for the surface antigen, and resulted in remarkable advances in knowledge of the virology and immunopathogenesis of hepatitis B and its associated chronic liver disease. In addition, the spread of infection can now be controlled in given circumstances, and more recently there have been far-reaching developments which include passive and active immunisation.

But despite the remarkably rapid application of these laboratory findings in clinical practice and preventive medicine a major problem remains unsolved. Hepatitis B virus has not been successfully propagated in tissue culture so that an *in vitro* assay system for infectivity is not available, and in its absence progress towards determining infectivity has been extremely limited. Only two species are known to be susceptible to hepatitis B, man and the chimpanzee. Infectivity cannot, and indeed must not, be experimentally measured in man, although some information can be deduced retrospectively in certain epidemiological settings and as a result of the application of newly developed sensitive serological markers which indicate exposure to the virus. Hepatitis B surface antigen and surface antibody were found in the serum of chimpanzees imported from Africa and living in captivity, suggesting that this species may be susceptible to hepatitis B infection. Experimental transmission of hepatitis B to a small number of previously unexposed chimpanzees established that the disease resembles clinically that in man and that the serological responses are identical. Although chimpanzees will be essential for assessing the infectivity, efficacy and safety of experimental hepatitis B vaccines now under development, there are many practical disadvantages to using them as animal models including their limited availability and expense. The world populations of the apes are already alarmingly small and these animals must be protected. Chimpanzees, although not as rare as the other apes, are being subjected to the combined threats of overhunting and the encroachment of civilisation, and they should be used with the greatest discretion for hepatitis studies (*Wld Hlth Org. tech. Rep. Ser.,* No 512, 1973; No 570, 1975).

Nevertheless, methods for determining infectivity are needed not only for the safety testing and evaluation of prospective hepatitis B vaccines but also for monitoring the removal of infectious virus from blood and blood products, for establishing physical and chemical methods of inactivation of

hepatitis B virus, and, of course, for the identification of infective carriers of the surface antigen of whom there are at a conservative estimate over 110 million (see *Nature,* **250,** 101; 1974).

It now seems that a potentially useful serological marker of relative infectivity may be available. This is a distinct soluble antigen, which although discovered in 1972 by Magnius and Espmark (*J. Immun.,* **109,** 1017; 1972), has until recently received little attention. The antigen—termed *e*—was found in some sera containing hepatitis B surface antigen and it differs immunologically and physicochemically from the previously described determinants of the surface antigen (Magnius, *Clin. exp. Immun.,* **20,** 209; 1975). Paradoxically, antibody against *e* has been found in serum specimens from healthy carriers.

The *e* antigen seems to be somehow intimately associated with the pathogenesis of liver damage. In other studies the *e* antigen was found by the immunodiffusion technique to be significantly more common in patients with chronic liver disease with persistent hepatitis B antigenaemia than in patients with acute viral hepatitis. Furthermore, the *e* antigen seemed to be a valuable prognostic marker since progression to chronic liver disease was recorded by serial liver biopsies in a number of patients with surface antigen-positive acute hepatitis associated with *e*. The clinical significance of the *e* antigen was supported by differences in the clinical, biochemical, and histological findings between patients with the *e* antigen and those without this antigen during the initial phase of viral hepatitis. The *e* antigen has also been found more frequently in surface antigen carriers with histological evidence of chronic liver damage. The presence of *e* antibody, however, is in general associated with only minor histological changes in the liver.

Other observations have also linked the *e* antigen with infectivity. It was commonly found in patients receiving treatment by maintenance haemodialysis and the antigen also appeared in the serum early in the incubation period of acute hepatitis B, at about the time of appearance of the surface antigen and before elevation of the serum transaminases. Furthermore, most of 12 healthy surface antigen carriers who had donated blood without producing clinical hepatitis in recipients possessed *e* antibody, which suggests that when this antibody is present the carriers may no longer be infectious.

Two very recent reports provide additional evidence for the relationship of the *e* antigen with infectivity. Okada and associates (*New Engl. J. Med.,* **294,**

Remarkable new beetle from central Italy

THE coleopterous fauna of Europe is undoubtedly better known than that of any comparable continental area in the world. By this time, to discover even a species new to science is a notable event in the life of a beetle collector; the discovery of a genuinely new genus in western Europe is something very few can hope to achieve. The finder of a new species representing a new taxon at higher than the generic level is almost unique in the last half century.

The fact that this has been achieved by Signor Roberto Pace of Verona, is not purely a matter of good fortune; he has been actively exploring a type of habitat which beetle collectors, except for a few in France, have largely neglected—the deeper layers of the soil. For the lack of an established English term for beetles of this type, we may adopt the French *endogées*. Endogean beetles have a good deal in common with cavernicolous ones—also studied mainly in France—and like them are scarcely represented in the British fauna. *Endogées* are usually small, eyeless, wingless, and more or less depigmented; from the obscurity of their habitat, very little is known about their foods or life cycles.

The insect discovered near Lazio in Central Italy by Pace (*Boll. Mus. civ. St. nat. Verona*, II, 445; 1975) represents not merely a new taxon of at least tribal level, but also a family and suborder hitherto unknown in the modern European fauna—and within the family and suborder represents a new and quite unexpected adaptive type. The suborder Archostemata, to which *Crowsoniella relicta* Pace belongs, is today a very small relict group, to which the oldest known fossils of Coleoptera (of Permian age, see Ponomarenko, (*The Historical Development of Archostematan Beetles*, Moscow, 1969)) have been attributed. Fossils of Archostemata are more or less numerous in "insect beds" throughout the Mesozoic era, but become much rarer in Tertiary deposits, more or less parallel to egg-laying mammals or Dipnoan lung-fishes.

Recent Archostemata are now placed in four small families (Crow-

son, *Boll Mus. civ. St. nat. Verona*, II, 459; 1975)· Ommadidae with one genus and two species in Australia; Tetraphaleridae with two species of *Tetraphalerus* in extra-tropical South America plus *Crowsoniella* in Italy; Cupedidae with four genera and about twenty species distributed through the main continental areas except for Europe and New Zealand; and Micromalthidae with a species in North America and a possibly distinct one in South Africa (Pringle, *Trans. R. ent. Soc. Lond.*, 87, 271; 1938). The larvae are definitely known to be woodborers in *Micromalthus* and a number of species of *Cupes* in America, Japan and Australia, and it is believed that this habit is general in the suborder. Except for *Micromalthus* and *Crowsoniella*, modern Archostemata are moderate-sized beetles with a body length rarely less than 7 mm, with well-developed wings, and active flight has been noted in several species.
Apart from *Crowsoniella*, the only record of subterranean habits in the group is for *Micromalthus*, found breeding in timbers of more or less deep mines in South Africa (Pringle, *op. cit*). However, species of *Tetraphalerus* have been collected in Argentina (Monros and Monros, *An. Soc. cient. Argentina*, 154, 19; 1952) in areas of bushy vegetation with no large trees, which would seem to be unlikely to furnish the fungus-attacked dead trunks and logs which

are the usual breeding grounds of *Cupes* species; it seems quite possible that *Tetraphalerus* breeds in dead roots underground. If so, the habits of *Crowsoniella* might appear as a natural development from those of *Tetraphalerus*.

The antiquity of the *Tetraphalerus* line is indicated by well-preserved fossils, apparently close to the recent genus, in Jurassic deposits of the USSR (Ponomarenko, *op. cit.*), and the Tertiary occurrence of the type in Europe is shown by the fossil *Tetraphalerites oligocenius* (Crowson, *Ann. Mag. nat Hist*, (B) 5, 147; 1962) from the Bembridge limestone of the Isle of Wight. The *Crowsoniella* line may well have evolved its flightless and subterranean adults in the Mediterranean region during the Tertiary era. In having antennal grooves above rather than below the eyes, *Crowsoniella* differs from *Tetraphalerus* but may resemble some of the Mesozoic fossils described by Ponomarenko—the separation of the two lines may even be of Jurassic origin. Unfortunately the head is not preserved in the fossil *Tetraphalerites*.

Crowsoniella is surely one of the most ancient elements in the hypogean fauna of Europe; the possibility remains that related types will eventually be discovered elsewhere, e.g. in the Balkan peninsula, or even the Crimea or the Caucasus, if and when systematic search for hypogean forms is undertaken in those areas.

746; 1976) examined for *e* antigen and antibody, serum samples from twenty-three pregnant women who were asymptomatic carriers of hepatitis B surface antigen. Ten mothers with *e* antigen and seven with *e* antibody were identified. Their babies were tested at intervals for over a year after birth. All ten babies born to mothers with the *e* antigen acquired the surface antigen

which persisted throughout the period of observation, and interestingly enough all ten elder siblings of these newborn infants were also found to be asymptomatic carriers. In marked contrast, all seven babies born to mothers with *e* antibody escaped infection with hepatitis B virus and none of their three elder siblings were surface antigen carriers. It was concluded that the

e antigen may be used as an indicator of transmission of hepatitis B virus from carrier mothers to their children Interesting results were also obtained by Grady and colleagues (*Lancet*, ii, 492; 1976) during a survey of medical personnel accidentally inoculated with blood containing hepatitis B surface antigen. Hepatitis B infection or a surface antibody response occurred in

60% when *e* antigen was detected in the inoculum compared with 31% when *e* antigen was not detectable. The *e* antigen was detected in 74% of inocula accidentally sustained in maintenance renal dialysis and transplantation units, which are recognised hepatitis "high risk" areas, compared with 20% in other clinical units and the resulting incidence of hepatitis was 22% and 6% respectively. It was pointed out that if the correlation of *e* antigen and infectivity is indeed better than indicated by the results of this study, and the correlation is not merely an indirect reflection of some more specifically related phenomenon, then improvements in the sensitivity of the test will be of great value and the potential application to the problems of the transmission of hepatitis B virus will be almost limitless. □

Soil structure discussions in Adelaide

from I. J. Smalley

> A meeting of the Soil Physics Commission of the International Society of Soil Science was held at the Waite Research Institute, University of Adelaide, on August 23–27, 1976. The topic was Modification of Soil Structure and the proceedings edited by W. W. Emerson, R. D. Bond, and A. R. Dexter) will be published by John Wiley, London.

AUSTRALIA is the driest continent and *it is* also the saltiest. This fact causes great problems for Australian agriculture, and for the new town builders at Monarto, particularly as the irrigation water often carries a significant proportion of dissolved salt. But a salty clay can make a good cricket pitch, as J. R. Harris (CSIRO Division of Soils) pointed out in his paper on the maintenance of soil structure under playing turf. Different sports impose widely differing conditions. The soil structure of a cricket wicket requires fine structured clays of high bulk density to be maintained in a condition in which plasticity is retained when wet. When dry, the bounce height of the cricket ball and the ability to withstand intensive playing wear at the surface are important characteristics to match against soil properties. At the other extreme of the soil structure scale, bowling and putting greens are generally constructed on coarse-structured sands where the emphasis will be

on free drainage of surface waters and free rolling of the ball.

Discussion of sporting applications however, occupied only a very small proportion of the meeting; sessions were held on forces between colloidal particles, soil geometry, soil strength, soil tillage, soil management, soil permeability, measurement of aggregate stability, organic matter and aggregate stability, oxides and soil aggregation, organic material and soil structure, modification of soil structure with organic polymers—in all over fifty papers were presented.

The use of soil conditioners (admixtures to preserve a desirable soil structure) was discussed at some length and the meeting was to a large extent a continuation of the annual discussions on soil conditioners (see *News and Views*, **258**, 483; 1975). There is growing interest in conditioners as they become more economic and are seen to be effective. Soil conditioning is based on several more or less basic phenomena. One is aggregation of soil particles, which itself depends on adhesion between particles and binding material. In nature, the adhesive product is humus, an ill-defined polymeric material originated by organic matter. Soil conditioners are chemically similar and indeed provide adhesive forces between soil particles. J. P. Quirk and A. M. Posner (Universities of Adelaide and Western Australia) and their co-workers presented recent data on polyvinyl alcohol, particularly with respect to adsorption behaviour on different soil colloids. It seems that there are significant conformational differences between polyvinyl alcohol adsorbed on clay surfaces and on the hydrated aluminium oxide, gibbsite.

Some fundamental studies on soil structure and strength were reported. J. N. Israelachvili and G. E. Adams (Australian National University) have measured the forces between two mica surfaces in KNO_3 solutions. The results exhibit all the essential features characteristic of an interaction involving repulsive double-layer forces and attractive van der Waals forces (see also *Nature*, **262**, 774; 1976). R. C. Foster (CSIRO Division of Soils) presented ultramicromorphological data on some South Australian soils. Soils from irrigated pastures contained large amounts of organic materials, mainly plant remains in various stages of decomposition. Phytoliths were common, but the soil largely consisted of highly compressed and distorted cell wall fragments containing much polyphenolic material. Layers of clay particles down to 0.1 m thick were trapped between the organic layers. Near living roots and also sometimes at considerable distances from them, polysaccharide

mucigels up to 20 μm thick occurred.

J. E. Lloyd (University of Sydney) described a torsional shear box designed to measure the strength of seed beds. The identification of interest of participating engineers and agriculturists was here most noticeably achieved. In general the engineers at the meeting probably learnt more from the agricultural specialists than *vice versa*, but now that the engineers have decided that soil structure at the single particle level is important no doubt they will contribute more and more to this developing subject. □

A hundred years ago

THE obstruction at the entrance to New York Harbour known as Hell Gate was successfully removed by an explosion of dynamite on Sunday afternoon without any of the disasters that many people anticipated. The mass to be removed was about 70,000 cubic yards. The number of borings was 3,500; the number of galvanic batteries 200, placed in an explosion-proof chamber at a distance of 200 feet from Hell Gate. The diameter of the borings was uniformly 3 inches, and the depth varied according to circumstances, from 3 to 11 feet. Fifty thousand pounds of dynamite were used. The shock was not perceptible, not even glass being broken. A vast volume of water and smoke was driven about fifty feet into the air. All the charges were exploded, and the rock is stated to have been thoroughly removed. The explosion was heard at a distance of ten miles, and a tremor like a slight earthquake was heard in New York City and the localities contiguous to Hell Gate. The work has been in progress for seven years.

EARTHQUAKES were felt on the night of September 12–13, at Salonica, and in South Italy, at Reggio. Two motions were observed in the last city, the first one being the most notable, both having taken place on the 13th, between 12 and 1 o'clock, local time. Another earthquake was felt at Salonica, on the 14th, at 5 o'clock in the morning. The Reggio commotions were propagated to Messina and vicinity. They produced quite a sensation, although not destructive.

THE splendid orang-utang in the Berlin Aquarium died last week of consumption. Its friend and playfellow, the chimpanzee, died the next day of consumption and grief. The young gorilla, the one living specimen ever brought to Europe, which we referred to some months ago, is still alive, but ailing. Hamburg not long ago offered 100,000 marks for the gorilla; it is feared that he will soon be sold for less.

Quantum field theory in curved space–time

P. C. W. Davies*

Recent theoretical developments indicate that the presence of gravity (curved space–time) can give rise to important new quantum effects, such as cosmological particle production and black-hole evaporation. These processes hint at intriguing new relations between quantum theory, thermodynamics and space–time structure and encourage the hope that a better understanding of a full quantum theory of gravity may emerge from this approach.

DURING the first quarter of this century, two major revolutions in physical science led to a complete restructuring of fundamental theoretical physics. The quantum theory met spectacular success in describing microscopic phenomena, such as atomic structure and chemical bonding. The theory of relativity, essentially a macroscopic theory, triumphantly explained the known discrepancy in the motion of the planet Mercury, and provided a basis for the understanding of cosmology. In its "special" form, applicable when gravity is negligible but velocities are large, the theory of relativity combines naturally with the quantum theory to yield a rich harvest of new results. The discovery of electron spin and antimatter arose directly out of this synthesis. So too did relativistic quantum field theory, which describes, for example, the interaction of electrically charged matter and electromagnetic radiation. This hybrid theory produced the modern conception of an elementary particle. The quantum field theory version of a particle differs in many respects from the classical notion of a little localised lump of energy. The prototype of the new version is the photon. It is the product of applying quantum theory to the electromagnetic field. Although the word "photon" conjures up the image of a tiny packet of light, this is quite misleading in a crucial respect. What is being quantised is not a localised object, but a mode of the wave field—something spread out over all of space.

The successful reconciliation of special relativity and quantum theory does not extend to the general case, where gravity is strong. Because the latter circumstances usually occur only in macroscopic systems, whereas quantum phenomena are microscopic, this mismatch has not been too serious in practice. In recent years, however, some interesting new possibilities have arisen, in which a proper understanding of quantum phenomena in strong gravitational fields might produce important advances in theory, and even lead to observational consequences.

The long term objective is to construct a full, consistent theory of quantum gravity, with the gravitational field itself quantised, perhaps after the fashion of the quantised electromagnetic field[1]. Even after many years of effort, this objective remains as elusive as ever. Sometimes it is conjectured that such theory would only be relevant on the minute length scale of 10^{-33} cm— the so-called Planck length, $(G\hbar/c^3)^{\frac{1}{2}}$—reducing the quantum gravity programme to a purely academic exercise. It now seems, however, that gravity may well lead to important quantum effects at much larger distances than this.

The basis for this new expectation is a study in which gravity

*Address: King's College, London University, Strand, London WC2R 2LS, UK.

is treated tentatively as a classical (unquantised) background field, in the presence of which all other fields are to be quantised. This somewhat easier approach is known as quantum field theory in curved space–time, because the unique status of the gravitational field as a geometric entity (the curvature of space–time) has encouraged a geometrical approach to quantum field theory, in the hope of a fresh perspective on formidable problems of principle. These problems always arise when the effects of external classical fields intrude into quantum field theory. It is hoped, though by no means certain, that the background field method represents a consistent first approximation, valid for distances much greater than the Planck length, to a (future) full theory of quantum gravity.

Although only tentative, this semi-classical treatment has nevertheless led to some unexpected discoveries, which may well point the way to a better understanding of the relationship between space–time structure and quantum theory.

Theoretical problems

Before describing those discoveries, it is necessary to explain the radical departures which the introduction of gravity into quantum field theory entails.

First, because the concept of "particle" is a global one, particle processes are sensitive to the global structure of the space–time. Ordinary quantum field theory depends heavily on the simple global properties of flat Minkowski space. Particles are defined successfully with reference to the underlying geometrical symmetries of this space. In a general curved space–time these symmetries are absent, and the notion of "particle" is without obvious meaning. Added to this is the problem that in general relativity, space–time may have new features such as horizons and singularities which must be taken into account in any satisfactory theory of quantum fields in curved space.

In certain simple cases, it may happen that the space–time possesses sufficient symmetry for a natural generalisation of the Minkowski space definition of a particle. This is so if the gravitational field is static, for example[2,3]. One distinctive state of a quantum field is that in which no particles at all are present. This is called the vacuum state. In Minkowski space the vacuum state is well defined, and corresponds intuitively to what we usually understand as a physical vacuum. In a more general space–time this is no longer true. What may be regarded as a vacuum in one reference frame (system of coordinates) may not be a vacuum in another frame. A very simple and dramatic illustration of this has been given by Stephen Fulling[3]. The essential features are present even in two-dimensional space–time, a diagram of which is shown in Fig. 1. An observer at

rest in the (t,x) frame follows the world line A. The other world line (B) corresponds to an observer who undergoes uniform proper acceleration to the right, for all time. His velocity relative to A approaches that of light for $t \to \pm \infty$. The light rays through the origin are drawn at 45° for convenience. Because information cannot propagate faster than light, these light rays act as an event horizon for B. He can never know about events which occur in the region marked "black hole". This appellation is used because the Universe in the direction of A would grow very dark as B zooms off to the right, on account of an escalating Doppler shift acting on any light travelling from A to B.

The space–time accessible to B is only a portion of the whole Minkowski space. It may be covered by a single coordinate system. In this portion, the space–time is still flat, but differs globally from Minkowski space because of the event horizon. It is a static universe, so that natural definitions of particle states and vacuum exist. Fulling showed that the vacuum state in this portion differs from the usual Minkowski space vacuum. This means that what A regards as a vacuum B does not. This has been interpreted by some[4] to mean that B will "see" particles, whereas A will not, a somewhat paradoxical idea. There is, however, no reason to suppose that the "particles" which B considers present correspond to "real" physical particles.
Fig. 1 The observer B undergoes uniform acceleration, while A remains at rest. The light ray through the origin to which B's trajectory is approaching forms an event horizon. B cannot see events above this line. This region of space–time is a "black hole"; light approaching B near this horizon becomes progressively more redshifted by the Doppler effect. The observer B has a completely different description of quantum particle states from that of A, who crosses into the black hole.

Using a simple geometrical argument, it is possible to show[5] that the spectrum of this mysterious radiation (in the massless case) is a Planck spectrum, corresponding to thermal equilibrium radiation at a temperature of $a/2\pi$, where a is the proper acceleration of the observer B. Recently, William Unruh has analysed the response of a simple model particle detector undergoing uniform acceleration, and confirmed that it does indeed detect thermal radiation at this temperature[6].

In this simple case, it is tempting to regard the unconventional vacuum as "unphysical". The enigmatic thermal radiation detected by B would then be dismissed as a disturbance caused by the agency which accelerates B. In a general space–time, however there is no easy way to single out one vacuum state over another. Nobody yet knows how to define a vacuum state in the general case.

The stress tensor

The ambiguities inherent in the concept of particles in regions of high space–time curvature has prompted an entirely different approach to quantum field theory in curved space[7]. In this new approach, one deals with mathematical objects which may be defined locally, and not globally as with particles. One important example is known as the stress–energy–momentum tensor, or stress tensor, for short. This object has the additional feature of acting as a source of gravity in Einstein's field equations, so that ultimately one might hope to be able to solve the theory of the coupled classical gravitational-quantum matter fields self-consistently.

Not all the difficulties associated with particle states are thereby circumvented, because the stress tensor must be calculated as an expectation value in some quantum state.

There are, however, several interesting situations in which, at some instant in the past, there exists a well defined vacuum state. The expectation value of the stress tensor can then be calculated in parts of the space–time which are strongly curved, as an expectation value in this initial vacuum state.

The simplest possible such case occurs if one starts with Minkowski space, and then disrupts it by introducing boundaries of some sort. This can be achieved in practice, for the electromagnetic field, using electrically conducting plates or mirrors, which reflect the field at their surfaces (see Fig. 2). If two such plates are held parallel and close, the Minkowski space vacuum is disturbed, even if the plates carry no electric charge. The reason is easy to understand. Modes of the field with wavelength greater than the separation of the plates cannot form as standing waves in the region between them, so they do not contribute to the vacuum energy.

It is easy to calculate the stress tensor between the plates. It was first done by Larry Ford[8]. The calculation does involve one fundamental and far-reaching subtlety, though. Formally, the stress tensor is infinite. This unpalatable circumstance is a result of the so-called "ultraviolet divergence", which is a universal problem in quantum field theory. It arises because even in the vacuum state, each mode of the field with frequency ω still has a zero-point quantum energy of $\hbar\omega$. Because the number of modes is infinite, the sum of all this energy is also infinite, progressively greater zero-point energy being contributed by the shorter wavelength modes.

In special relativity, this is no problem, because only differences in energy are observable. And the differences between empty Minkowski space and that with the parallel plates is finite. After subtracting away the divergent part Ford discovered that there was a uniform, static negative energy density between the plates. One consequence of this result is

Fig. 2 The Casimir Effect. Relative to the surrounding vacuum the space between the parallel conducting plates has negative energy, spread in a uniform cloud between the plates. It results in an electromagnetic force of attraction between the plates even though they are electrically neutral and there are no photons present.
that an electromagnetic force of attraction should exist between the mirrors, even though they are electrically neutral. This effect had been known for many years, and is called the Casimir effect. It was predicted in 1948 by H. B. G. Casimir[9] and has since been measured experimentally[10].

If the mirrors are allowed to move about, a new phenomenon occurs. The static energy density between the plates is augmented by a flux of energy arising from the surface of the moving mirror. In a two-dimensional model, it is possible for the stress tensor to be calculated exactly in terms of functions implicitly dependent on the mirror trajectory[11]. If the system eventually becomes static once more, particle states may be defined in that future region, and the new phenomenon may be described as particle creation by the moving mirrors. This particle creation is present even for a single moving mirror.

The moving mirror models are useful in that they display in the simplest possible way some of the essential features of how the vacuum state may be disturbed by geometrical effects. When space–time curvature is allowed, similar phenomena occur.

Cosmology

Astronomy provides two scenarios in which gravity is strong enough to stimulate important quantum effects. The first is gravitational collapse, the second is big-bang cosmology.

The pioneering work on the cosmological case was carried out by Leonard Parker in the late 1960s. He showed that particles are created in an expanding universe, though exceedingly inefficiently in present conditions[12]. The motion of the universe acts in much the same way as the motion of mirrors, by disturbing the static vacuum. The more violent the motion, the greater the production rate.

During the early stages of the cosmological expansion, the expansion rate was enormously faster than now. At very early times, say 10^{-23} s—long before the Universe had even reached the reasonably well understood lepton era—this production may have been so prolific that it drastically modified the cosmological dynamics. In particular, if the expansion was anisotropic (different in different directions), then the effect of the particle production may have been to "smooth" out the anisotropy. It is a curious unexplained feature that the present condition of the Universe is one of high isotropy. There are hopes that this may now be understood as a result of the back-reaction of quantum effects. Very detailed studies[13,14] by the Russian astrophysicists Ya B. Zeld'ovich, A. A. Starobinskii and V. N. Lukas encourage these hopes.

It is important to realise that in the curved space case, the particle production occurs out of empty space. It does not arise from sources, or even from moving surfaces. The curvature of space–time itself may be caused by the presence of matter, but this matter does not directly cause the particle production.

Cosmological models have provided important "testing" scenarios for quantum stress tensor calculations (refs 13–16 and unpublished work of J. S. Dowker, R. Critchley, P.C.W.D. and S. A. Fulling). But now a host of new problems arises. Infinite terms which depend on the space–time curvature occur that cannot be removed by subtracting away the infinity which is already present in the Minkowski space case. Some of these terms have the same geometric structure as the left-hand side of Einstein's field equations, so they can be regarded as simply "renormalising" the values of the Newtonian gravitational constant G or Einstein's cosmological constant, albeit by an infinite amount. Other infinite terms cannot be so treated, and require a modification of the field equations to accommodate them. On top of all this the finite part of the difference (and perhaps some additional infinite terms) seems to contain ambiguities, which depend on the method by which the infinities are subtracted. There is no doubt that these ambiguities, which are probably inherent in the whole theory, present a major obstacle to understanding the subject. To remove the ambiguities, it is necessary to appeal to principles outside quantum field theory. Although there is no general agreement on what principles to invoke, very reasonable expressions for the stress tensor have been obtained by these methods (P.C.W.D., and S. A. Fulling, unpublished). For example, it seems certain that there is precisely no creation of photons in an homogeneous, isotropic universe, although there is probably still a non-zero vacuum energy density due to the space–time curvature.

Black holes

Gravitational collapse provides a rare opportunity for the application of quantum field theory because the space–time is approximately flat in the distant region where an observer would be located in practice. For this reason, the asymptotic situation may be described in terms of particles.

A study of this apparently very complicated problem has been carried out by Stephen Hawking[17], with very far-reaching consequences. The collapse, of a spherical star for example, disturbs the initial vacuum of the quantum field, and induces a flux of particles out of the collapsing object. The situation is closely analogous to the accelerated observer shown in Fig. 1. An event horizon forms around the collapsing matter; there is an infinite redshift from the surface. In this case B corresponds to the distant (inertial) observer who watches the collapse. The result is the same. He sees a flux of thermal radiation coming from the black hole. The temperature of this radiation is quite independent of the details of the star or its collapse history; it depends only on the mass M of the star through the formula

$$T = \frac{\hbar c^3}{8\pi GMk} \simeq 10^{-6} \left(\frac{M_\odot}{M} \right) K$$

More complicated expressions have also been derived for rotating and electrically charged black holes.

This astonishing discovery by Hawking has provided an enormous stimulus to the whole subject of quantum field theory in curved space. It also has profound implications in a wider sense. The created particles constitute a radiation flux in the asymptotic region where space–time is flat. This time the flux can, therefore, be unambiguously interpreted as a real flux of energy, coming out of the black hole. It follows that the black hole must shrink as its mass decreases. But as M falls, the temperature rises. Eventually the black hole apparently disappears in an explosive burst of radiation. In practice, only black holes of microscopic size, such as may have been formed early on in the big bang, will have suffered this fate, for a solar mass black hole has a temperature of a mere 10^{-6} K, and quantum effects are negligible.

The fact that black holes have a temperature implies that they are, in some sense, in thermal equilibrium. This means that they may be treated using thermodynamics. Direct analogues of the laws of thermodynamics were already known to apply to black holes even before Hawking's discovery[18]. Now these laws can be placed on a sound footing and new properties of black holes may be discovered[19]. For example, it turns out that rotating or charged black holes undergo a thermodynamic phase transition at high values of angular momentum or electric charge. Although it is only a conjecture, many people believe that Hawking's result heralds the discovery of important new connections between gravity, thermodynamics and quantum theory, with implications far beyond the subject of black holes.

Several enigmas remain. What does an observer who falls into the black hole see? How does the radiation react back on the hole, causing it to shrink? Where exactly is the radiation produced? What happens to the baryons which went to make up the collapsing star, which apparently disappears completely?

To answer these questions it is necessary to know what is happening near, and inside, the black hole, where the space–time curvature is comparable to the relevant radiation wavelengths and the particle concept breaks down. Some useful facts

emerge from a calculation[20,21] of the stress tensor. So far, this has only been done in two-dimensional models, though the essential features of the Hawking process are still present.

The results show that, in the reference frame of an observer at fixed distance from the centre of the star, the star seems to be surrounded by a cloud of static negative energy. This energy density is sometimes called vacuum polarisation, and is similar to that between the conducting plates in the Casimir effect. It is caused by the static space curvature around the star, and falls off rapidly with distance from its centre. If the star now implodes, a steady flux of energy is superimposed on this static cloud. At great distance this flux is the only contribution to the stress tensor and represents the Hawking radiation. The flux term arises mainly from the surface, and also the interior, of the star. This does not mean however, that particles are created there. Particles are not well defined in this region.

As the star shrinks inside the event horizon, the negative energy cloud around the star can stream into the black hole, causing its mass, and size, to decrease. The precise effect that this has on the collapsing matter is still uncertain.

The separation into flux and vacuum polarisation terms is really somewhat artificial, because it depends on the reference frame used by the observer. If the observer falls into the black hole, the situation is very different. He sweeps through the vacuum polarisation as he falls, so it appears to him no longer a static cloud but an outgoing flux of negative energy. By the time he reaches the event horizon, this flux is comparable in magnitude, but opposite in sign to the Hawking flux. Thus, he does not see much of the radiation which appears to his colleague out at infinity. This is consistent with the analogous situation shown in Fig. 1. There the inertial observer A who, you will recall, sees no particles in Minkowski space, corresponds to the falling observer who enters the black hole.

In practice, the quantum fields which are most important for the black-hole evaporation are the massless ones—electromagnetic, neutrino and, paradoxically, the gravitational field itself. If gravitons exist, they too will be radiated. Calculations[22] show that 2% of the luminosity will be due to gravitons, 17%

to photons and 81% to neutrinos. If the black hole rotates, the graviton flux is greatly enhanced. The Hawking effect thus produces the extraordinary situation that graviton processes are comparable in efficiency to electromagnetic processes. Rather than being restricted to the relatively uninteresting scale of 10^{-33} cm it is seen that on the much larger scale of say, 10^{-14} cm, full quantum gravity effects cause significant changes in the behaviour of strongly gravitating systems. These changes could be observed in principle; for example, by measuring the change in the orbital radius around the Sun of a mini black hole of mass about 10^{14} g. The rate of increase around the Sun of the orbital radius would depend sensitively on the mass loss rate, including that due to gravitons.

The new results of the past five years have enormously increased interest in quantum gravity. In spite of its highly esoteric nature, this subject is already seen to provide important new advances in hitherto unrelated subjects, such as black holes, thermodynamics and cosmology. The next five years can be expected to produce more advances still.

Geology and late Cainozoic lake sediments of the Suguta Trough, Kenya

P. H. Truckle

Geology Department, Bedford College, Regent's Park, London NW1 4NS, UK

A consideration of the geological evolution and late Cainozoic lake deposits of the Suguta Trough in Kenya shows that for the later part of its history the growth of Lake Suguta was probably independent of that of Lake Rudolph, but was influenced instead by climatic change.

THE Suguta Trough (Fig. 1) is the northward continuation of the axial trough of the Kenya Rift. At this latitude the main rift is an ill-defined wide zone of faulting 130 km across. Northwards the trough passes into the southern end of the Lake Rudolph (renamed Lake Turkana) Basin,

and has its structural continuation in the Lake Stephanie Trough[1]. At present the Suguta and Lake Rudolph troughs are separated by the Barrier Volcanic Complex. The northern end of the Suguta Trough is an arid area of internal drainage occupied by the saline Lake Logipi and subject to seasonal flooding. The surface of this lake is 118 m below the 1968 level of Lake Rudolph[2]. The Suguta river is the only permanent supply of surface water to the trough, but Lake Logipi is maintained during the dry season by sub-surface flow through the alluvium flooring of the trough.

Only the upper part of the volcanic sequence is described here (Pliocene to Recent); it comprises alternating basalt

and trachyte volcanism. The Suguta Trough was first initiated less than 3.0 Myr ago, and was subsequently filled in by younger volcanic products. The reforming of this trough, less than 0.75 Myr ago led to the eventual development of Lake Suguta.

Champion[3] has noted the occurrence of sediments flooring the trough and of wave-cut platforms on the southern side of the barrier, and has concluded that the two lakes were continuous before they became separated by growth of the barrier. Once separation was complete, Lake Suguta disappeared because of the insufficient water supply from the Suguta River relative to the evaporation rate. Reconnaissance studies of the Suguta sediments, and preliminary determinations of strand line altitudes, indicate that around 9,600 yr BP Lakes Sugata and Rudolph occupied apparently separate basins. The Recent history of Lake Suguta may have been dependent on climatic change rather than on an enlarged Lake Rudolph overflowing into the Suguta Trough.

Geological evolution

The geology of the Western Suguta Scarp is shown in Fig. 2.

Nathelot Basalts. These are the Lopiripira basalts of Rhemtulla[4]. A new name for this formation is proposed since the hill of Lopiripira is composed entirely of Nasaken trachyte agglomerate, and the basalts are typically developed at Nathelot. The basalts lie over older, tilted volcanic sequences, and the lava pile has the form of a large, low-angled shield. Nasaken trachytes underlie the Nathelot basalts and have yielded ages largely in the range 5.7–5.4 Myr, but younger dates for this volcano overlap with the age for the basal basalt flows[5]. A single basalt flow from this formation has given an age of 4.5 ± 0.4 Myr.

Loriu Trachyte Group. These trachytes lie conformably over the Nathelot Basalts and comprise three separate quartz trachyte volcanoes (Lopogut, Lomi and Kalakopon) whose alignment parallels that of the Suguta Trough. South of the Kamuge River, the Kapatagne Trachytes occupy a similar stratigraphic position[4]. The trachytes have given ages of 3.0 ± 0.2 Myr (Lomi), 4.4 ± 0.2 Myr (Kalakopon) and 3.3 ± 0.2 Myr (Kapatagni). The Tirr Tirr Trachyte and Basalt Group occurring on the eastern margins of the trough[6,7], has been dated at 3.6–3.9 Myr (ref. 8), suggesting it is broadly contemporaneous with the Loriu Trachyte Group. These trachytes are the northern and eastern extension of the South Turkana trachytes of Webb and Weaver[5].

Monoclinal downwarping of the Loriu and Tirr Tirr groups led to the initiation of a proto-Suguta Trough.

Lorikipi Basalts. This basalt formation erupted from the floor of the trough, infilling and locally overflowing the structure. A single K–Ar determination of 4.0±0.1 Myr cannot be reconciled with the observed sequence.

Namarunu and Kamuge Trachytes. To the north, a mottled green trachyte flow and welded tuff sequence can be traced from the Loriu Plateau to the base of the Namarunu Trachyte Volcano some 300 m lower within the Suguta Trough. These trachytes lie over the Lorikipi Basalts but predate the next phase of faulting. To the south, the Kamuge Trachytes occupy a similar strati-graphic position, and a welded ash flow tuff has yielded an isotopic age of 0.75±0.1 Myr. The Kamuge Trachytes correlate with the lower flows from Emuruangogolak, whose activity commenced before the Suguta Trough reformed.

Kamuge Basalts. These crop out on the Loriu Plateau and are downwarped and downfaulted into the Suguta Trough. A K–Ar determination of '0' Myr indicates the youth of these basalts.

Monoclinal downwarping and minor faulting (between the Kamuge River and Lomi), passing into normal step faults, recreated the western Suguta scarp. The eastern Suguta Scarp was formed by a monoclinal downwarp and associated faulting[6,7].

Following this last event, volcanism became restricted to the floor of the Suguta Trough and included the Suguta Basalts, member C basalts, and the continued eruption of Emuruangogolak and the Barrier, although the detailed geology of this complex is not well known. Incision of the Kamuge River system preceded the deposition of the Suguta Beds.

The Suguta Beds

Sediments occurring within the Suguta Trough and post-dating the latest phase of trough formation, have been designated the Suguta Beds. They comprise three sedimen-tary and one volcanic member (Fig. 3). The Suguta Beds are well exposed and crop out over wide areas of the Suguta Trough floor.

Member A is observed only in the vicinity of Kamuge, and is a dominantly clastic sequence of variable particle size. Rapid lateral facies changes, numerous minor unconformities and washouts indicate a fluviatile environ-ment. Member A is overlain with marked unconformity by member B diatomites.

Member B is well displayed at Kamuge and Gwasinyono Arrolio, where it is overlain by member C basalts. A similar sequence is seen at Kainagokin. At Kamuge, an essentially 'pure' diatomaceous sequence is overlain by silts, pebbly silts and silty diatomites, and at Gwasinyono Arrolio, a uniform sequence of bedded diatomites and intercalated pillow lavas occurs. Locally, grits underlie these diatomites.

Members A and B were tilted and downfaulted towards the axis of the trough and subject to erosion before the eruption of member C basalt.

Member C is represented by subaerial basalts resting unconformably on member B. At Gwasinyono Arrolio these basalts are intercalated with basal member D sediments and pass into the more extensive basalt field, capping the Namarunu trachyte volcano. Similar relation-ships obtain on the northern side of Emuruangogolak. To the east of Gwasinyono Arrolio, and at Kainagokin member C is faulted, although the relationship of the tectonic episode to member D sediments is not clear.

Member D at Gwasinyono Arrolio is a lower clastic sequence which overlies member C and is itself overlain by a thin sequence of well-bedded diatomites. The grain size of the clastic sediments decreases towards the trough axis. Thin diatomaceous deposits overlie member C at Kamuge and Kainagokin. Infrequent diatomites overlie member C basalts on Namarunu at an altitude of around 600 m. They contain gastropod remains, and are asso-ciated with algal limestones and wave cut basalt agglu-tinate cones. The gastropods have yielded a ^{14}C date of 9,660±210 yr b.p. (unpublished).

Members B and D record two separate phases of lacustrine sedimentation. During each phase Lake Suguta initially deepened but its development was terminated by desiccation which led to faunal extinction and was followed by subaerial erosion and volcanicity. Remains of *Croco-dylus, Lates* sp. and, rarely, gastropods (*Melanoides tuberculata*) and bivalves were found within members B and D. Rolled and badly worn bones were noted in the conglomerates of member A. The presence of elements of the Lake Rudolph/Nilotic fauna within members B and D suggests a hydrographic link between Lake Rudolph and Lake Suguta.

Lake levels

It is not possible at present to evaluate the effects of any deformation which may have affected strand lines within the trough. Within the Suguta Trough, high level lake benches occur at altitudes of up to 600 m. The 9,660-yr

date (member D) is of the same order as the 9,000±yr, climatically induced high stand of many East African lakes[*]. On the eastern Suguta Scarp, lake benches have been reported up to 550 m (refs 6 and 7) and up to 575 m on the southern side of the Barrier[10]. The age of these benches is not known. Butzer and Thurber reported[11] heights of 450–455 m for the highest deposits of the Kibish Formation (Omo area, Lake Rudolph), whose age range (27,444–5,450 yr BP) encompasses the value for member D. Although the chronology of the high level strand lines within the Suguta Trough is not well known it is possible to make some inferences about the relationship of Lake Suguta to Lake Rudolph, based on the assumption that the strand lines of the Suguta Trough have not been significantly deformed.

The differences in altitude between the Lake Suguta and Lake Rudolph strand lines suggest that from member D times at least, the Barrier complex was sufficiently well developed to prevent the two lakes coalescing. The present minimum altitude of the Barrier is 834 m (ref. 10), and it is questionable whether direct overflow of either lake across this complex could have taken place during member D times. An alternative outlet for Lake Suguta could be established by flooding the Kamuge River system, which would overflow into the Kerio river and subsequently into Lake Rudolph. Along the Kamuge river, infrequent diatomites occur at altitudes up to around 600 m. Overflow into the Kerio River would be possible should Lake Suguta levels reach an altitude of around 606 m. The sedimentary record indicates two major cycles in the development of Lake Suguta. This is more consistent with lake growth independ-

ent of Lake Rudolph rather than the progressive desiccation of an arm of Lake Rudolph, cut off by the growth of the Barrier.

Finally, it should be noted that it was apparently the present arid nature of the Suguta Trough which impressed Champion[1]. Under the prevailing climatic conditions inflow into the Suguta Trough is insufficient to maintain a large permanent lake, but during the 9,000-yr BP wet phase, Lake Baringo is likely to have supplied increased amounts of water to the Suguta Trough[8]. This increase of overflow from Baringo would further supplement the growth of Lake Suguta, already enlarged by climatic change throughout its drainage system. The rivers of the Suguta system can be expected, during this phase, to have had more permanent flow regimes than at present.

Significance of major Proterozoic high grade linear belts in continental evolution

F. Bryan Davies
Department of Geology, City of London Polytechnic, Jewry Street, London EC3N 1ND, UK

Brian F. Windley
Department of Geology, University of Leicester, Leicester, UK

Major Proterozoic high grade linear belts are broadly conformable and sub-parallel to Archaean trends. Some are marginal to Archaean cratons, others intracratonic. All belong to a major set extending across the middle to late Proterozoic supercontinent. They are broadly contemporaneous with hairpin bends of polar wander curves, and some controlled igneous activity. Some are intracontinental structures developed in Proterozoic times when the deeper levels of continental masses underwent internal movement without loss of general coherence.

HIGH grade mobile belts may have formed in the overriding thickened plate on one side of continent–continent collision boundary[1] or they may have developed by reactivation of earlier Proterozoic or Archaean 'basement' rocks[2,3]. Data

relevant to the problem include the lack of offset of earlier oblique structures across several African belts[4], palaeomagnetic apparent polar wander curves suggesting that the bulk of Africa was an integral crustal unit throughout the Proterozoic[5,6] and Laurentia in the early Proterozoic (Hudsonian)[7,8] and divergent polar wander curves that indicate that the Grenville Belt formed at a plate convergent boundary[7,9] (this is inconsistent with the basement reactivation model[10] and with other palaeomagnetic data[11]). Palaeomagnetic evidence[1-13] suggests that there may have been a supercontinent throughout Proterozoic times (from 1,000 to 2,200 and possibly 2,700 Myr BP), but this has been challenged[14].

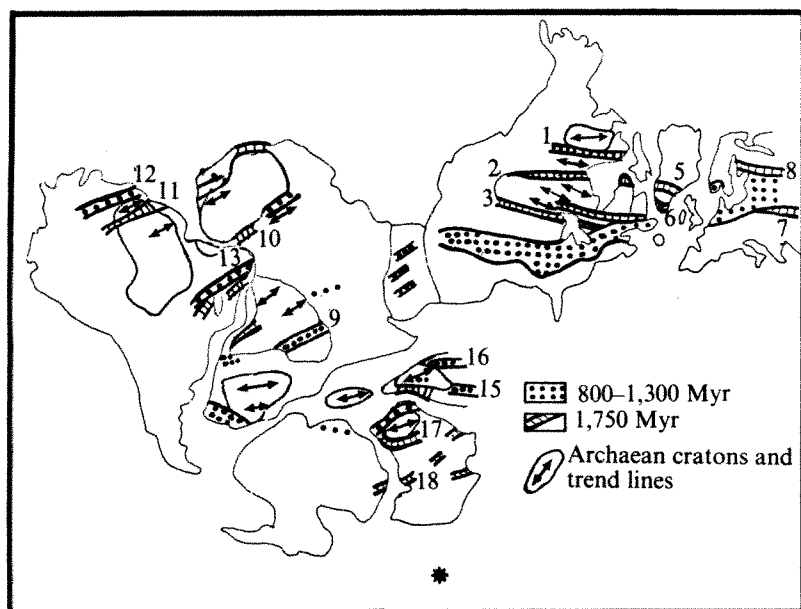
We produce here a plot of high grade Proterozoic mobile belts on the proposed supercontinent (Fig. 1), which, although problematic, is probably more relevant than the Permo-Triassic assembly of Pangaea (Gondwanaland rotated 180° between the Cambrian and the Permian[15]). We have not plotted the late Proterozoic Pan-African belts, because


Fig. 1 Map of the mid–late Proterozoic supercontinent, palaeomagnetically determined by Piper[11–13], showing the distribution of two ages of Proterozoic lineaments lying on small circles about a point of rotation(∗) off the coast of Australia. Key to the major lineaments: 1, South-east margin of Slave Province[19,24]; 2, Nelson River, NW Superior Province; 3, SE Superior Province; 4, Grenville Front (and south-west extension)[10]; 5, Magssugtoqidian, Greenland (and unmarked Laxfordian of North-west Britain)[27–29]; 6, Ketilidian[27–29]; 7, Central Europe line[37]; 8, Karelide–Sveccofennide margin[38]; 9, Karagwe–Ankolan and Kibaran belts of central Africa; 10, Eburnian, east margin of West African craton[30]; 11, Amazon depression between Guyana and Brazillian Shield[35]; 12, North of Guyana Shield[35]; 13, Pre-Mines belts, Brazil[30,38]; 14, Eastern Ghats, east India[30,38]; 15, Satpura[30,38]; 16, Arivalli-Dehli belts, Peninsula India[39]; 17, Frazer belt[19,40]; 18, Adelaide belt[19,40].

so far they have been determined largely on radiometric evidence[16], nor the many low grade early Proterozoic geosynclines like Circum-Ungava and Hamersley, that contain banded iron formations[17] and probably formed as narrow Red Sea-type rifts according to palaeomagnetic[7,8] and stratigraphic evidence[18] with possible minor subduction. Neither of these types of belts, both discordant to our general trend, are considered here. In producing our plot (Fig. 1) we are neither attempting to validate the concept of a supercontinent nor denigrating the possibility that plate convergence contributed to the formation of some Proterozoic belts. We do suggest, however, that the sub-parallel distribution of so many belts in Fig. 1 places certain constraints on the movement of plates in the Proterozoic. Our principal aim is to emphasise that the high temperature nature of many of the mobile belts indicates that the continents suffered internal ductile strain under steep geothermal gradients often along transcurrent zones during the Proterozoic[19]. The lineaments we discuss could form either in the interior or margin of a thickened overriding plate of a collision-pair or within a large drifting continent or supercontinent[19]. Much structural[4,20] and palaeomagnetic evidence[5,6] favours the drift during much of Proterozoic time of several large continental sheets that suffered some marginal deformation giving rise, for example, to the Coronation[21] and Mount Isa[22] geosynclines, but more importantly, to internal ductile deformation along many discrete shear zones and mobile belts. Detailed structural studies[23] show that several major shear belts in western Greenland record transcurrent displacements that took place at some depth within a single continental mass. It is likely that this intraplate deformation is a reflection of the ductile nature of much of the Proterozoic continental mass —an intermediate stage between the widespread permobile activity in the Archaean and the more rigid behaviour of plates in the Phanerozoic, when mobile belts were confined to plate margins and internal deformation was brittle.

We use the term lineament here to include shear belts, mobile belts and linear zones of transcurrent displacements of magnetic and gravity anomaly patterns. These are high temperature belts, distinct from low grade geosynclines and high level faults.

Lineament development before 1,300 Myr BP

The lineaments of North America and the North Atlantic region are probably some of the best documented[19,24], and together fall into a number of types. Several intracratonic

lineaments strike north-eastwards across the Southern Superior Province and seem to be sub-parallel to the Grenville Belt. These lineaments deflect the Archaean structural, aeromagnetic and gravity patterns of the greenstone belts, and are traversed by undeformed members of the McKenzie Dyke swarm, dated at about 1,200 Myr BP. Some lineaments, particularly the craton marginal set were sites of granite emplacement or basic-acid volcanism during the mid-Proterozoic[25]. They therefore compare in broad age to the time span of such lineaments in the high grade terrains of the Canadian Shield as the western Superior, south-eastern Slave[26], and North Atlantic region. Of these, at least the Nagssugtoqidian of Greenland[23,27] and the Laxfordian of north-western Britain[28] were sites of transcurrent displacements and basic dyke emplacement in late Archaean and early Proterozoic times. Both these lineaments became the junctions between regions stabilised about 2,700 Myr BP and younger Proterozoic mobile belts[29]. In the later development of both lineaments, displacements perpendicular to them accompanied by granitic intrusions became prominent by about 1,600 Myr BP. It may be that this later stage is expressed in the Ketilidian Mobile Belt, which is dominated by displacements along the craton margin, and by considerable granite emplacement[27]. When plotted on a reconstruction of the continents before continental drift, the lineaments at the margin of the North Atlantic region, including those of eastern Scandinavia, fit the directions of both the intracratonic and marginal lineaments of the Canadian Shield[19,28]. Our argument is supported by the general coherence of palaeomagnetic poles from the Canadian Shield, which suggest that internal blocks did not move by large amounts relative to one another during the Hudsonian Orogeny when the shield seems to have undergone internal lineament deformation without loss of general coherence[7–9,14].

Early Proterozoic linear mobile belts are widespread in the Gondwana group of continents[11,19] and are mainly of the craton-marginal type. In Australia they form the junctions between the Yilgarn and Carpentaria blocks. Near-parallel structures occur in Antarctica, and the Eastern Ghats of eastern India. The Eburnean Belt lies along the eastern margin of the West African Craton and has a possible extension in South America, north of the Guyana Shield. The Ubendian and the older Limpopo belts in central and southern Africa are, however, oblique to this general trend.

The early Proterozoic lineaments seem to share a common evolution. Most probably they originated in the late

Archaean or early Proterozoic as transcurrent dislocations with associated basic dyke swarms which in several lineaments could fit the regional pattern. The development of the lineaments seems to have been arrested with the cratons at this early stage. Further development occurred in the lineaments along the margins of the cratons. In several lineaments of the North Atlantic Province a change from transcurrent displacements to movements perpendicular to the craton margins[37] was marked by an increase in granitic emplacement both along the lineaments and in broader zones parallel to them within the larger mobile belts. The culmination of mid-Proterozoic mobile belt development is probably marked by the intrusion of anorthosites, alkali complexes and rapakivi granites marking a major belt extending from the western USA to the Urals, which ceased not long after 1,300 Myr ago[35].

Lineament development between 1,300 and 1,000 Myr BP

Although the development of the last group of lineaments seems to have been arrested before 1,300 Myr BP, a number of narrow zones of basement reactivation and wider belts of tectonism and igneous activity developed between 1,300 and 1,000 Myr BP (ref. 30). The Grenville Belt and its possible extensions in North America and Europe is wider and more extensive than all other lineaments. Palaeomagnetic data[12] cast doubt on the concept that the formation of this belt involved some lateral plate motion[7-9].

A number of linear zones of this broad age can be outlined as anomalous structural, igneous and radiogenic features in Gondwanaland. These form a set of parallel lineaments concordant with the line of the contemporaneous Grenville Belt projected as a major zone extending through western Arabia, central Africa and along the eastern coast of South America (see Fig. 1), and with most of the earlier lineaments dating from around 1,700 Myr BP. Some belts, for example the Aravalli-Delhi Belt were active in both periods. The development of these 1,300–1,000 Myr lineaments has much in common with the later stage of development of the earlier lineaments, particularly in the association of major tectonism, the basic dyke emplacement about 1,200 Myr ago, and the syn- and post-orogenic granite emplacement and widespread thermal events.

Discussion

These Proterozoic lineaments seem to be coherent, global-scale, structures which belong to a single, broadly conformable pattern for about 1,000 Myr. Major events in the evolution of each age group of lineaments seem broadly contemporaneous with the hairpin bends of the single polar wander track for North America and Africa at 1,700 Myr BP and 1,300–1,000 Myr BP (refs 11 and 31), and therefore seem related to major changes in position of the Proterozoic continents or supercontinent. Many lineaments evolved as transcurrent dislocations within formerly continuous continental crust, rather than as sutures marking closed oceans.

In the context of a single Proterozoic supercontinent[11-13] both age groups of lineaments fit as zones of transcurrent displacement which lie on small circles about a point of rotation off the Australian part of the early continent. This agrees broadly with the interpretation of the Coronation[21] and Mount Isa[22] geosynclines and the Belt-Purcell Series of western North America as continental margins developed on the opposite leading edges of the rotated supercontinent.

Following the formation of the belt of anorthosites and rapakivi granites, the culmination of lineament development was expressed by late Proterozoic rifts, as in the Gardar Province of southern Greenland, which controlled lava extrusion, clastic continental sedimentation and the intrusion of alkaline complexes. These rifts may also be seen as the earliest expression of continental breakup connected with the eventual formation of the Proto-Atlantic Ocean in late Proterozoic times; they are comparable with the Triassic rifts containing continental sediments and volcanics along the Atlantic coast of the USA[32]. In fact, the large number of failed rifts and aulocogens of late Proterozoic age[33] is probably a demonstration of how difficult it was to fragment the Proterozoic supercontinent. Both types of Proterozoic lineaments are, on a global scale, sub-parallel to the trends of the Archaean granite–greenstone belts and therefore could be influenced by the overall Archaean structural pattern[34]. A few Proterozoic lineaments seem to have incidentally influenced the form of some Phanerozoic orogenic belts (for example, the old Amazon depression shield lineament segmenting the Andes along the Amotape Zone[35]).

Besides simple collision, there are several other means of explaining the formation of different Proterozoic high grade belts. Evidence from the shear belts is consistent with, but does not necessarily suggest, the idea that they are the deep-seated equivalents of modern intracontinental transform faults[36]. The Grenville Belt has been considered as the result of the slow drift of a continental plate over one or a series of hot spots, giving rise to successive stages of extension and compression. At deep levels of erosion an aulocogen may appear as a high grade ensialic mobile belt with some degree of transcurrent movement[42]. Upwelling and diverging convection currents may give rise to high heat flow and the formation of ensialic belts[43].

Sex hormone receptors in mammary tumours of GR mice

Mels Sluyser, S. G. Evers & C. C. J. De Goeij

Division of Endocrinology, The Netherlands Cancer Institute, Antoni van Leeuwenhoek-Huis, Amsterdam, The Netherlands

Studies of the growth behaviour and hormone receptor contents of GR-mouse mammary tumours suggest that the hormone responsive tumours are mixed populations of hormone-dependent cells and autonomous cells. The hormone-dependent moiety of these tumours contains high levels of progesterone receptor and oestrogen receptor. The autonomous moiety has a low but probably significant oestrogen receptor level, and is practically devoid of progesterone receptor. Androgen receptor levels in both moieties are low. Endocrine ablation prevents growth of the hormone-dependent moiety of the tumours, but not of the autonomous moiety.

IN approximately one-third of patients with metastatic breast cancer, the tumour responds favourably to ablative or additive forms of endocrine therapy[1]. Several groups of investigators have shown that a relationship exists between the presence of specific oestrogen-binding proteins in human breast cancer tissues and hormone responsiveness of the tumour[1-4]. But although assays of oestrogen receptors have important prognostic value, a large

proportion of the oestrogen receptor-positive group does ont respond to endocrine treatment[5]. Similarly, studies on DMBA-induced mammary tumours in rats suggest that determination of cytoplasmic oestrogen-binding capacity alone does not perfectly predict whether the growth of a tumour will be affected by ovariectomy[6].

It has been proposed that in non-responding receptor-positive cases the oestrogen receptor can bind hormone but cannot subsequently cause gene activation, and that assays of progesterone receptor may have greater prognostic significance[7]. It has also been suggested that determination of androgen receptor may be an important tool for predicting response to castration in premenopausal patients[8].

To evaluate the roles of different hormone receptors in mammary tumour growth, it is important to have available model systems with which the influence of each factor can be established. The GR-mouse system seems to be useful in this respect. Hormone-dependent mammary tumours can be induced in ovariectomised GR mice by continuous treatment for 3–4 months with oestrone and progesterone. The tumours can be transplanted into castrated $(O20 \times GR)F_1$ hybrid mice which are treated with oestrone and progesterone. The tumours generally retain their hormone dependence during the first transplant

generation, but in subsequent transplant generations a progressive decrease in hormone dependence is observed which eventually leads to complete hormone independence. An advantage of using this system is that a certain tumour can be studied in various endocrine conditions. We have reported[9] previously that the mammary tumours which respond to oestrone and progesterone contain higher levels of oestrogen receptor than the autonomous mammary tumours. We now present results of a study on the relative concentration of oestrogen receptor (OR), progesterone receptor (PR) and androgen receptor (AR) in these tumours, and the relationship with tumour growth behaviour.

Transplantation series

Mammary tumours were induced in ovariectomised GR mice and tumour lines developed by serial transplantation from seven separate primary tumours (tumour lines I–VII). The degree of hormone responsiveness of the primary tumours and of each transplant generation was tested by grafting portions of the tumours in two castrated mice which were treated with oestrone and progesterone (OPC mice), and two castrated mice which were not treated with hormones (C mice). Tumours which were transplantable in OPC mice but which did not yield visible outgrowths within 3 months in the C mice were designated hormone dependent (HD). Tumours which were transplantable in both cases but which yielded outgrowths in OPC mice sooner than in C mice, were designated hormone responsive (HR). Tumours which grew equally well in OPC as in C mice, were designated autonomous or hormone independent (HI).

Samples of 500-mg tumour tissue were used for hormone-receptor assay. 2,4,6,7-n-^{3}H-Oestradiol (85 Ci mmol^{-1}) was obtained from the Radiochemical Centre. R5020 (17,21-dimethyl-19-nor-pregna-4,9-diene-3,20-dione), ^{3}H-R5020 (51.4 Ci mmol^{-1}), R1881 (methyltrienolone) and R1881-6,7-[3]H (58.2 Ci mmol^{-1}) were gifts of Dr J. P. Raynaud, Roussel-Uclaf. Nafoxidine hydrochloride (U 11,100A) was a gift from the Upjohn Company. Determination of oestrogen receptor in the tumour cytosols was carried out with the dextran-coated charcoal assay[10,11]. The same method using ^{3}H-R5020 was used for progesterone receptor assay[12], and with ^{3}H-R1881 for androgen receptor assay[13]. Controls contained excess non-radioactive ligand. Protein was assayed according to Lowry *et al.*[14]. Recep-

tor levels were expressed as fmol mg^{-1} cytosol protein. Tumour tissues stored at $-70\ ^{\circ}$C were used for receptor assays, since in cytosol preparations sometimes losses of OR and PR were found to occur up to 0.2 and 0.8% d^{-1}, respectively, when these were stored at $-70\ ^{\circ}$C.

Figure 1 shows the results obtained with transplantation series I–VII. As a parameter of the growth of each individual tumour we calculated the ratio $(\log_e M)/t$, where M was the weight (mg) of the tumour when it was collected (usually about 3,000 mg), and t was the time (d) after grafting. Six of the primary tumours were found to be HD, since they were transplantable in OPC mice but not in C mice; transplantation series I–VI were developed from these tumours. The seventh primary tumour was found to be autonomous, since its first transplant generation appeared equally rapidly in OPC mice and in C mice; this line (tumour line VII) was therefore discontinued. Tumour lines I–IV and VI exhibited a decrease in hormone dependency after the second to third transplantations, but line V remained HD up to the ninth transplant generation.

When HR tumours were grafted in C mice (Fig. 1, dotted lines), they gave rise to tumours with markedly lower $(\log_e M)/t$ values than when they were grafted in OPC mice (Fig. 1, solid lines). This was due to the fact that in the C mice the tumours appeared after a longer lag period than in the OPC mice. The tumours which appeared in C mice had significantly lower PR and OR contents than those which were obtained in OPC mice. Evidence that the tumours derived from C mice were autonomous was obtained by transplanting portions of 6 of these tumours in OPC mice and C mice. As is shown in Fig. 2, oestrone and progesterone did not cause an increase in the $(\log_e M)/t$ values of the transplants. Furthermore, the tumours remained HI during subsequent serial transplantations, whether or not hormones were given, and their receptor contents remained low.

These results indicate that in the absence of oestrone and progesterone, the HD cells in a hormone-responsive graft did not multiply, and that the HI cells in the graft consequently gave rise to autonomous outgrowths. The long lag period can be attributed to the long time required for the small percentage of HI cells in the graft to form a visible tumour (Fig. 3b). This suggests that all tumours indicated in Figs 1 and 2 by open circles are autonomous.

Hormone dependent   Hormone responsive   Hormone independent
(Autonomous)

Fig. 3 Serial transplantation of mammary tumours in castrated GR mice (C), and in castrated GR mice which were treated continuously with oestrone and progesterone (OPC). Tumours indicated by R were found to have high hormone receptor contents, those without R had low hormone receptor contents. A possible interpretation is given in the lower part of the figure. Shaded cells are hormone dependent, unshaded cells are autonomous. The scheme proposes that mouse mammary tumours progressively become less hormone dependent during transplantation because there is an increase in the percentage of autonomous cells in the tumours. When a hormone-responsive tumour is growing in

the presence of hormones (*a*) both the hormone-dependent cells and the autonomous cells can multiply, whereas in the absence of hormones (*b*) only the autonomous cells can multiply. Case *b* therefore yields an autonomous tumour with low receptor values. It is not clear whether the primary hormone-dependent tumour from which the transplantation series is derived is entirely devoid of autonomous cells or already contains minute amounts of autonomous cells. Both alternatives are illustrated at the bottom left.

Receptor levels and ratios

Figure 4 shows the average values and standard deviations of receptor contents of hormone-dependent, hormone-responsive and autonomous tumours. The levels of PR and OR were both markedly lower in HI tumours than in HD or HR tumours. No significant difference in hormone-receptor content was found between HD and HR tumours. The results indicate that PR levels below 17 fmol per mg cytosol protein and OR levels below 14 fmol per mg cytosol protein were markers for hormone independence. Androgen-receptor levels in HD and HR tumours were markedly lower than PR and OR levels in these tumours. AR levels in HD and HR tumours were on average slightly higher than in HI tumours. Figure 4 also shows the results obtained when the PR/OR ratio of each tumour was calculated separately, and the average values and standard deviations of the data were computed. HD and HR tumours had significantly higher PR/OR ratios than HI tumours. No significant difference in PR/OR ratios were found between HD and HR tumours. The results indicate that PR/OR values smaller than 0.8 were markers for hormone independence.

Discussion

Calculation of PR/OR ratios served as an additional check for the significance of absolute PR and OR values. A suitable marker for hormone independency in GR-mouse mammary tumours seemed to be PR and OR contents lower than 17 and 14 fmol per mg cytosol protein, respectively, together with a PR/OR ratio lower than 0.8. It should be pointed out that these values apply to the method used for receptor assay in which only the number of free receptor sites was determined. In the OPC

mice the endogenous levels of both progesterone and oestrogen would be very high, so the quantitative levels of free cytosol receptors could be small compared with the bound receptor.

At present it is not clear whether the level of cytoplasmic hormone receptor can be taken as a measure of the number of cells in the tumour that contains the receptor. To substantiate this conclusion, other methods such as autoradiography should be utilised. If this assumption is correct, however, our data are consistent with the assumption that hormone-responsive mouse mammary tumours are heterogeneous and that they contain the following cell populations. (1) Hormone-dependent cells with average PR, OR and AR contents of 74, 48 and 6 fmol mg^{-1} cytosol protein, respectively, and an average PR/OR ratio = 2.0. These cells depend for growth on oestrogen and progesterone. The hormone-dependent population might consist either of one cell type with all three receptors, or might contain different cell types with different receptor contents. There is evidence for the presence of different stem lines in hormone-dependent rat mammary tumours[15]. (2) Hormone-independent (autonomous) tumour cells with average PR, OR and AR contents of 3, 9 and 1 fmol mg^{-1} cytosol protein, respectively, and an average PR/OR ratio = 0.4. These cells are not affected by endocrine ablation.

The results obtained with the GR-mouse model system reveal some of the limitations of hormone-receptor assay as a parameter on which to predict whether the growth of a mammary tumour will be affected by endocrine treatment. One of these limitations is that whereas low PR, OR and PR/OR values seemed to be a good indication for hormone independence, high PR, OR and PR/OR values did not reveal whether or not the tumours contained autonomous cells in sufficient quantity to

Fig. 4 Hormone-receptor contents of mammary tumours of GR mice. Receptors of progesterone (PR), oestrogen (OR) and androgen (AR). Receptor levels are expressed in fmol per mg cytosol protein. PR/OR, progesterone receptor/oestrogen receptor content ratio (mean ±s.d.). Hormone-dependent (HD), hormone-responsive (HR) and hormone-independent (HI) tumours.

contribute significantly to growth behaviour. Thus no essential difference in receptor levels was found between HD tumours and HR tumours (Fig. 4). Furthermore, tumours which became autonomous after serial transplantation in OPC mice usually still had significantly higher receptor contents than autonomous transplants derived from C mice (Fig. 1).

Variations in sampling also impose limitations on the significance of receptor assays. We often found marked differences in receptor values between different samples taken from one hormone-responsive tumour. If these reservations also apply to hormone-responsive breast cancers in human patients, they might contribute to the high percentage of clinically defined non-responding positives.

The finding that autonomous mammary tumours of GR mice generally had small but significant amounts of OR, but practically no PR, is of interest. Since in oestrogen target tissues the synthesis of PR depends on the action of oestrogen[16], it seems possible that in some autonomous mammary tumours of GR mice the lesion is at the nuclear level. For instance, this might be the case with some autonomous tumours of transplantation series I which had OR levels about equally high as some hor-

mone-responsive tumours of other lines (Fig. 1). This possibility has, however, to be investigated further.

Rotational diffusion of band 3 proteins in the human erythrocyte membrane

R. J. Cherry, A. Bürkli, M. Busslinger & G. Schneider

Eidgenössische Technische Hochschule, Laboratorium für Biochemie, ETH-Zentrum, CH8092 Zürich, Switzerland

G. R. Parish*

Eidgenössische Technische Hochschule, Institut für Zellbiologie, ETH-Hönggerberg, CH 8093 Zürich, Switzerland

Band 3 proteins rotate in the human erythrocyte membrane; rotation is almost certainly confined to an axis normal to the plane of the membrane and is characterised by a diffusion coefficient of the order of 1,000 s⁻¹. Spectrin does not restrict rotational motion of band 3 proteins.

MANY, and probably most, cell membranes contain lipids arranged in a bilayer configuration. According to currently popular concepts of membrane structure, 'intrinsic' or hydrophobic membrane proteins are essentially solutes in the fluid lipid bilayer[1]. As such they would be expected to undergo free diffusion—that is, diffusion the rate of which is determined only by the size of the protein and the 'viscosity' of the membrane. There is good evidence that this is the case for rhodopsin where Cone[2,3] has measured both lateral and rotational diffusion constants. In other instances there is qualitative evidence that proteins diffuse rather rapidly in the plane of the membrane (for reviews, see refs 4–6). On the other hand, at least one membrane protein, bacteriorhodopsin, is completely immobilised by protein–protein interactions[7–9]. At the present time, it is by no means clear to what extent proteins do diffuse freely and to what extent free diffusion is restricted by interactions with other components of the membrane, or conceivably of the cell—for example, microtubules or microfilaments.

To investigate this question, it is necessary to have available a technique which measures diffusion quantitatively and can be applied generally. In the case of rotational diffusion of membrane

proteins, rotational motion characterised by relaxation times at least as slow as microseconds has been both predicted and demonstrated[1,6]. This causes an experimental difficulty since such a time range is not adequately covered by established techniques of measurement. Indeed, investigation of the rotational diffusion of membrane proteins has only so far been possible with a very limited number of proteins which possess special spectroscopic properties[1,5–7].

To overcome this difficulty, we have developed a new technique for measuring slow rotational diffusion, which exploits the long lifetimes of triplet states of organic molecules[7,10,11]. Using the method of flash photolysis, triplet (or other long lived) states may be detected by transient absorbance changes after flash excitation. If the exciting light is plane polarised, the absorbance changes are in general dichroic. The rate of decay of dichroism gives information about the rate of rotational motion of the excited molecules.

Since most proteins do not naturally possess a suitable chromophore for such measurements, it is necessary to attach an artificial chromophore, or probe. Eosin (2,4,5,7-tetrabromofluorescein) is a favourable choice of probe since the four bromine atoms promote intersystem crossing. Covalent coupling to proteins may be achieved using the reactive isothiocyanate derivative (eosin–NCS). From studies with protein–eosin conjugates dissolved in viscous solutions, we have concluded that reliable measurements of rotational relaxation times in the microsecond–millisecond time range may be made using the flash photolysis method[10,11]. Here we report the first application of the method to proteins in a cell membrane.

The human erythrocyte membrane was chosen for these studies because the composition and properties of its proteins are relatively well characterised[12–14]. Major constituents are spectrin, a fibrous protein composed of two polypeptides of

*Present address: Department of Plant Sciences, University of Leeds, Leeds LS2 9JT, UK.

molecular weights 220,000 and 240,000, and band 3 (otherwise known as component *a*). Band 3 consists of hydrophobic proteins which span the membrane, have a molecular weight of about 90,000 and comprise about 24% of the total membrane protein[12]. They are implicated in anion and other transport functions[15-18]. The major sialoglycoprotein, glycophorin, also spans the membrane and has been extensively characterised[14]. It is thought that glycophorin in association with band 3 constitutes the membrane particles revealed by freeze-fracture electron microscopy[19,20].

Labelling of human erythrocytes with eosin–NCS

Red blood cells obtained from fresh or recently outdated human blood were washed three times with 310 mosM sodium phosphate buffer, *p*H 7.4. Packed cells (15 ml) were incubated with 3 mg eosin–NCS for 3 h at 22 °C. The cells were then washed twice more with isotonic buffer to remove any unreacted label and subsequently haemolysed in 40–50 volumes 20 mosM sodium phosphate buffer, *p*H 7.4. The ghosts were sedimented by centrifugation for 20 min at 20,000*g* and washed three to four times with 20 mosM buffer. All operations except the labelling step were carried out at 0–4 °C.

The amount of bound eosin was determined spectrophotometrically as described previously[10,11], after first solubilising ghosts with SDS. Protein was determined using the method of Lowry *et al.*[21]. Typically the ghosts contained 0.5–1.5 μg eosin per mg protein.

The proteins labelled by the above procedure were identified using SDS–polyacrylamide gel electrophoresis and by selective extraction experiments (details presented elsewhere). Briefly, SDS–polyacrylamide gel electrophoresis was carried out in a manner similar to that described by Fairbanks *et al.*[22]. Using gels of dimensions 0.85 × 8 cm loaded with 0.5 mg protein it was feasible to locate eosin fluorimetrically. Eosin fluorescence was located predominantly in the region of band 3. A small amount of eosin was also associated with bands 1 and 2 (spectrin). There were negligible amounts of eosin bound to other proteins. Using gels made from solutions containing 7.5% acrylamide (w/v), 2.73% *bis*-acrylamide (with respect to acrylamide), it was possible to separate glycophorin from band 3. In this way we could demonstrate that little or no eosin was bound to glycophorin.

These results were further confirmed using selective extraction procedures. Selective extraction of bands 1, 2 and 5 by incubation at low ionic strength in the presence of EDTA[22], demonstrated that less than 10% eosin was associated with these components. On the other hand, extraction with Triton X-100 (ref. 23), which has partial selectivity for band 3, released up to 80% eosin from the membrane. Finally the labelled ghosts were extracted with chloroform–methanol (2:1) as described by Hamaguchi and Cleve[24]. The amount of eosin extracted with lipids into the organic phase was negligible. A few per cent eosin appeared in the aqueous phase together with the membrane sialoglycoproteins.

The selective labelling which we have observed is in accord with other authors who find that only band 3 and sialoglycoproteins are available at the outer surface of the red cell[12, 25-27]. Since some of our label is associated with spectrin, we conclude that there is some permeation of eosin–NCS through the membrane. We found little labelling of glycophorin, and a similar observation was made by Cabantchik and Rothstein[15] with 4,4'-diisothiocyano-2,2'-stilbene disulphonic acid (DIDS). DIDS (added to intact cells) is found to bind almost exclusively to band 3 with less than 5% of the label associated with glycophorin.

The number of eosin molecules bound per protein is relevant to the possibility of energy transfer between eosins. For 1 μg eosin per mg total membrane protein, it may be estimated that the mole ratio eosin: band 3 would be 1:2 if all the eosin were bound to band 3 (assuming band 3 has a molecular weight of 90,000 and comprises 24% of the membrane protein).

Rotational diffusion measurements

Excitation of eosin at 540 nm by a laser light pulse of duration 1–2 μs and energy 100–200 mJ results in transient absorbance changes in the sample. Either positive absorbance changes (conveniently measured at 610–650 nm) due to triplet–triplet absorption or negative changes (measured at 500–525 nm) due to ground state depletion, may be detected. When the exciting source is plane-polarised, the absorbance changes are dichroic provided rotational motion is slower than the instrumental response (2–3 μs)[10,11].

Transient absorption changes from eosin-labelled ghosts are shown in Fig. 1. The better signal-to-noise ratio of the ground state depletion signal is due to the higher extinction coefficient of the singlet–singlet transition compared with the triplet–triplet transition. Both absorption and depletion signals demonstrate the existence of a rather long lived dichroism. All quantitative evaluation of the data was carried out with depletion signals.

The data were analysed by calculating the anisotropy factor *r*(*t*) given by

$$r(t) = (A_{pa}(t) - A_{pe}(t))/(A_{pa}(t) + 2A_{pe}(t)) \qquad (1)$$

where $A_{pa}(t)$ and $A_{pe}(t)$ are respectively the absorbance changes at time *t* for light polarised parallel and perpendicular to the exciting flash. The time dependence of *r* is shown on a semi-

Fig. 1 Transient absorbance changes from eosin-labelled ghosts. Membranes suspended in 20 mosM phosphate buffer, *p*H 7.4, temperature 22 °C. Eosin concentration 7 μM, 0.9 μg eosin per mg protein. Before measurement, samples were bubbled with argon for 10 min to displace oxygen. *a*, Triplet–triplet absorption measured at 650 nm; *b*, ground state depletion measured at 525 nm. In each case the stronger signal is obtained with the measuring beam polarised parallel to the exciting flash, the weaker signal for perpendicular polarisation. The flash photolysis apparatus was described in ref. 11.
Fig. 2 Time dependence of the anisotropy parameter r calculated from depletion signals similar to those shown in Fig. 1b. For more accurate calculation the difference between the parallel and perpendicularly polarised components is displayed directly using the differential input of the oscilloscope amplifier.

logarithmic plot in Fig. 2. It is clear that the decay of dichroism contains at least two components. Within the experimental uncertainty $r(t)$ is independent of time at long times so that the observed time dependence of r takes the form

$$r(t) = r_1 \exp(-t/\varphi_1) + r_2 \qquad (2)$$

Replotting $\log(r(t) - r_2)$ against t gives $\varphi_1 \approx 0.5$ ms. (The data are not sufficiently accurate to determine φ_1 precisely; conservatively, we consider the above value to be correct within a factor of 2.)

Interpretation of data

Consideration of the magnitude of the flash photolysis signals leads us to conclude that a high proportion of eosin molecules in the sample must contribute to the observed dichroism. Since we have shown that eosin is mainly bound to band 3, we can relate the dichroism data to the rotational motion of these proteins.

Equations which evaluate $r(t)$ for an irregular body in an anisotropic medium are not currently available. Various authors have, however, solved the problem of the time dependence of r for an irregular body in isotropic solution[28-31]. If we assume that the rotational motion of band 3 proteins may be characterised by two diffusion constants, D_{pa} for rotation about an axis normal to the membrane and D_{pe} for rotation about either of the two perpendicular axes, then the problem formally becomes equivalent to the rotation of a body with an axis of symmetry immersed in an isotropic medium. We can therefore use existing theoretical treatments to evaluate our data. An additional simplification arises with depletion signals because the same transition moment is used for excitation and measurement. (The lowest absorption band of eosin is a single transition and triplet–triplet absorption is relatively small at 525 nm (refs 10 and 11).) The theoretical expression for $r(t)$ then becomes

$$r(t) = \sum_{i=1}^{3} A_i \exp(-E_i t) \qquad (3)$$

where $A_1 = 6/5 \sin^2\theta \cos^2\theta$, $A_2 = 3/10 \sin^4\theta$, $A_3 = 1/10(3\cos^2\theta - 1)^2$, $E_1 = 5D_{pe} + D_{pa}$, $E_2 = 2D_{pe} + 4D_{pa}$, $E_3 = 6D_{pe}$, and θ is the angle between the transition moment and the axis of symmetry. (The theoretical expressions given in refs 28–31 all become equivalent for the case considered here.)

We consider that there are two main interpretations of the two experimentally observed components in the decay of $r(t)$. Since band 3 proteins seem to offer different labelling sites on either side of the membrane[12,25-27], it is likely that they have a negligibly small rate of rotation about an axis in the plane of the membrane. The existence of a carbohydrate moiety on these proteins, which is only detectable on the outside surface, points to the same conclusion[16,32,33]. Thus we anticipate that $D_{pe} \approx 0$ and equation (3) then gives

$$r(t) = A_1 \exp(-D_{pa}t) + A_2 \exp(-4D_{pa}t) + A_3 \qquad (4)$$

Thus, the time-independent component of the experimental $r(t)$ curve may be identified with A_3 and is due to the negligibly small value of D_{pe}. ($r(t)$ will of course eventually go to zero due to rotation of the whole erythrocyte ghost; the relaxation time of this process is, however, of the order of seconds.) The measured time constant φ_1 is then related to D_{pa}; the experimental accuracy is, however, clearly insufficient to detect the two expected components.

An alternative explanation of the data is that the eosin-binding sites are heterogeneous. (Note, however, that the amount of eosin associated with spectrin is too small to account for one or other component.) In particular, it cannot be ruled out that there is some aggregation of band 3 proteins in the membrane. In this case r_2 could correspond to aggregates which are too large to have an appreciable rotation on the time scale of the experiment.

If the first explanation is correct, we could in principle determine θ (which is likely to be a mean value), since $r_2 = A_3$. This is, however, dangerous since even if protein aggregation is not the main reason for the time-independent dichroism, it may well make a contribution. (The observation that the relative magnitudes of r_1 and r_2 vary from one preparation to another makes us suspicious that this may be the case.) We therefore prefer not to attempt to determine θ (and therefore the coefficients A_1 and A_2) and to regard φ_1 as an unknown combination
Fig. 3 Inner fracture faces (IFF) of ghosts before and after spectrin depletion ($\times 36,000$). a, Unlabelled, untreated, pH 7.6; b, eosin-labelled, untreated, pH 7.6; c, eosin-labelled, spectrin-depleted, pH 7.6; d, eosin-labelled, spectrin-depleted, pH 5.4. Eosin labelling as in text. Spectrin was depleted by incubating 1 part packed ghosts with 10 parts 20 mM phosphate buffer, pH 8.5, (containing 0.5 mM NaN$_3$) for 18 h at 37 °C (ref. 43). Samples were maintained at 0–4 °C at all times except during labelling and spectrin removal. For electron microscopy, samples were mounted on precooled gold disks and frozen in liquid Freon. Freeze fracturing was carried out in a Balzer's apparatus at a temperature of −100 or −105 °C. Specimens (without etching) were replicated with Pt–C and backed with C, both evaporated from electron beam guns. Replicas were examined in a Phillips 200 electron microscope.

of $1/D_{pa}$ and $1/4D_{pa}$. On this basis a value of 0.5 ms for φ_1 implies D_{pa} is in the range 500–2,000 s^{-1}.

Band 3 is probably involved in anion transport across the erythrocyte membrane[15,16,34]. Lepke *et al.*[35] find that sulphate exchange is completely inhibited when 1.7×10^6 molecules of the irreversible inhibitor dihydro 4,4′-diisothiocyano-1,2-diphenyl-ethane-2,2′-disulphonic acid (H$_2$DIDS) are bound to band 3. This figure implies a turnover number for chloride exchange of about 2×10^4 per s per site if all these sites are involved in transport. If only a portion of these sites are responsible for transport then the turnover number must be higher. Thus a rotation time in the order of tens of microseconds or faster would be required if transport occurred by a rotational mechanism. Irrespective of any particular interpretation, the present experiments do not detect any component of rotational motion of band 3 in this order of magnitude. Thus if band 3 is responsible for anion transport, a mechanism involving rotation of the whole protein is ruled out. This is hardly a surprising conclusion; as discussed above, arguments based on the structure of band 3 also indicate that rotation across the membrane is improbable[16,25]. Nevertheless, the present studies demonstrate how rotation measurements may be useful in elucidating transport mechanisms in other systems where the outcome is not so easily anticipated.

'Viscosity' of the membrane

Whatever the precise interpretation of the data, a component of rotational motion of band 3 proteins of the order of 0.5 ms is clearly present. The only existing quantitative determination of the rotation of a membrane protein is Cone's measurement with rhodopsin[2], which yielded a relaxation time of 20 μs at 20 °C. Rotation of band 3 proteins in the human erythrocyte membrane clearly is markedly slower.

We found that addition of glycerol to a concentration of 60% to the membrane suspension had no detectable effect on φ_1. Since this addition increased the medium viscosity by a factor of 10, we may conclude that the rotation of band 3 proteins is a function of the membrane viscosity. If we regard band 3 proteins as cylinders of radius a, then the friction coefficient for rotation about the axis of symmetry is given by (ref. 36)

$$f = 4\pi a^2 h \eta \tag{5}$$

where h is the depth of the cylinder immersed in the membrane and η is the membrane viscosity.

Fig. 4 Effect of spectrin removal on the time dependence of the anisotropy parameter r. Temperature 22 °C. ×, Control sample, pH 7.6; ●, spectrin-depleted ghosts (prepared as described by Fairbanks *et al.*[22]), pH 7.6; △, spectrin-depleted ghosts, pH 5.4. The lower initial value of r for the control sample is due to experimental factors and has no special significance. Essentially similar results were obtained when spectrin was depleted using the procedure of Elgsaeter and Branton[43].
From the Einstein relation[37]

$$D = kt/f \tag{6}$$

we obtain

$$D_{pa} = kt/4\pi a^2 h \eta \tag{7}$$

If we take a as the radius of the particles revealed by freeze-fracture electron microscopy (40 Å) and h as the thickness of the hydrophobic core of the membrane (40 Å), then a value of $\varphi_1 = 0.5$ ms implies $\eta = 25 - 100P$ (remembering that the respective contributions of $1/D_{pa}$ and $1/4D_{pa}$ to φ_1 have not been determined). This is considerably higher than previous estimates of the viscosity of the erythrocyte membrane based on measurements of methanol diffusion[38] and fluorescence polarisation[39,40]. It may indicate that the 'microviscosity' experienced by small molecules dissolved in the hydrocarbon region of the lipid bilayer is quite different from that experienced by a protein which may interact with the whole length of the lipid molecules.

Probably the replication procedure used in freeze-fracture electron microscopy leads to an overestimate in the size of the particles[41,42]. If the true radius of band 3 proteins is less than 40 Å, then the calculated viscosity will be increased to still higher values.

Interaction between band 3 and spectrin

The above discussion of membrane viscosity only has validity if band 3 proteins undergo free diffusion in the membrane. Apart from the possibility of self-association of these proteins discussed above, possible interactions with other components of the membrane have also to be considered. In particular, there is evidence that spectrin restricts lateral diffusion of intramembrane particles[43]. It has been proposed that these particles contain both glycophorin and band 3 and are physically linked to spectrin[19].

We have investigated the effects of spectrin removal on rotational diffusion of band 3 proteins. We have depleted eosin-labelled ghosts of spectrin using the procedure of incubation at low ionic strength described by Elgsaeter and Branton[43]. Figure 3 shows freeze-fracture electron micrographs of unlabelled ghosts, eosin-labelled ghosts and spectrin-depleted ghosts, all at pH 7.6, together with spectrin-depleted ghosts at pH 5.4. The distribution of particles is little different in the labelled ghosts compared with the control, demonstrating that the labelling procedure in itself does not cause any marked aggregation. In agreement with Elgsaeter and Branton[43], the distribution of particles in spectrin-depleted ghosts is little altered at pH 7.6 but massive aggregation occurs on lowering the pH to 5.4.

Spectrin is most efficiently and selectively removed by incubation at low ionic strength in the presence of EDTA. Using the procedure of Fairbanks *et al.*[22] we have also prepared spectrin-depleted ghosts in this manner. SDS–polyacrylamide gels confirmed that most of bands 1, 2 and 5 were selectively released from the membrane. When examined by electron microscopy it was clear that considerable vesiculation of the membranes had occurred, as noted by other authors[44]. The effects of pH on particle aggregation was, at far as could be ascertained, essentially similar to that shown in Fig. 3.

Spectrin-depleted ghosts prepared by both methods outlined above were examined by flash photolysis. Essentially similar results were obtained in both cases; one set of data is shown in Fig. 4.

Inspection of Fig. 4 clearly shows that there is no detectable rotational motion in spectrin-depleted ghosts at pH 5.4. This is entirely reasonable in view of the strong aggregation of particles in these conditions as seen in Fig. 3. Large aggregates would be expected to have negligible rotation on the time scale of the experiment. This correlation between rotational motion and the state of aggregation of the particles further demonstrates that we are making valid measurements of rotational motion of band 3 proteins (or alternatively, provides further evidence that the particles contain band 3 proteins).

The most interesting conclusion which arises from the results in Fig. 4 is that there is no detectable difference in rotational motion between spectrin-depleted ghosts and control ghosts when the *p*H is maintained at 7.6. In other words, there is no evidence that spectrin restricts the rotational diffusion of band 3 proteins. Although this finding does not completely rule out a direct linkage between band 3 and spectrin, it does place severe restrictions on the type of attachment which can be envisaged. Only a linkage which permits free rotation of band 3 about an axis normal to the plane of the membrane is compatible with the present measurements.

On the other hand, we consider that a model in which there is no direct interaction between band 3 and spectrin accounts equally well for all the mobility data. Suppose that band 3 proteins protrude from the membrane in the spaces between the spectrin fibres. It follows that lateral diffusion over large distances would be prevented by the spectrin network, whereas rotational diffusion would be unaffected. The enhanced aggregation of membrane particles in spectrin-depleted ghosts at low *p*H (ref. 43) would be explained by such a model. Further, proteins entrapped within the spectrin network would probably follow any redistribution of the spectrin molecules themselves. The clustering of anion sites[45] and concanavalin A receptors[19] on the outer membrane surface which is observed when spectrin is aggregated may be explained in this way.

Peters *et al.*[46] labelled proteins (principally band 3) with fluorescein, bleached one half of a single ghost and looked for the spread of fluorescence from the unbleached to the bleached half. No spreading was detected, placing an upper limit on the lateral diffusion constant of 3×10^{-12} cm^2 s^{-1}. For free diffusion such a low value would imply a rotational relaxation time of the order of 50 ms, a value clearly incompatible with our 0.5 ms component of rotational motion. This again implies that lateral diffusion is restricted and is entirely compatible with a model of band 3 proteins trapped in the spectrin net.

Our results emphasise the importance of clearly distinguishing local diffusion from diffusion over large distances. The fact that the latter is not observed does not necessarily imply that proteins are immobilised. If the membrane is 'compartmentalised' then rapid diffusion over small distances may still occur and in turn may have functional significance.

We thank Professor G. Semenza for encouragement, Dr K. Razi Naqvi for discussions and the Swiss NSF for support.

letters to nature

Optical behaviour of HDE226868 during a Cyg X-1 X-ray transition

As part of regular monitoring of variable X-ray sources with the University College London–Mullard Space Science Laboratory X-ray instrumentation on the Copernicus satellite, we have observed Cyg X-1 continuously for 12 d between 22 October and 3 November, 1975. The X-ray flux was noted to be more variable than it had been during previous monitoring runs, when the source had been in its low state[1], and, in particular, a marked increase in flux occurred 8 d into the observing run (~ October 29.5 UT, 1975). After this date, the mean 3–8-keV flux increased steadily, and by 3 November had risen by 30% compared with its level during the first part of the observation. The X-ray flux data, integrated in time blocks of 30 min, are shown in Fig. 1b. In Fig. 1a we show the spectral hardness ratio (defined as the 5.5–8.0-keV flux divided by the 3.0–5.5-keV flux) integrated over intervals of 0.5 d. This quantity decreased

progressively after 30 October, until by 3 November it was down by an amount equivalent to a drop of 0.1 in the power law spectral index of the source.

Holt *et al.*[2] and Grindlay *et al.*[3] have also noted an increase in the X-ray flux of Cyg X-1 at about this time. These two groups found the sources to be up to five times stronger than the

Table 1 Best-fit parameters and χ^2

Interval	χ^2 per degree of freedom	Mean ($m_{\rm B}$)	Semi-amplitude ($m_{\rm B}$)
A	23.9	9.644	0.025

All 1975 data	22.0	9.652	0.020
Fig. 1 Copernicus X-ray data for Cyg X-1 during October–November 1975. *b*, X-ray flux binned into 30-min intervals; *a*, spectral hardness ratio in 0.5-d bins. The error bars correspond to $\pm 1\sigma$ in each plot and there is a systematic uncertainty of up to 0.1 in the power law index indicated on the right-hand ordinate of *b*.

level seen earlier in October, a maximum equivalent to $\simeq 1,500$ Uhuru counts being seen on 6 November[3]. Continued observation with the Ariel V satellite[4,5] has shown that Cyg X-1 maintained a relatively high flux level until late February, when the intensity dropped by a factor of three[5].

The blue-band optical magnitude of HDE226868, the spectroscopic binary BO1b star which is the optical counterpart of Cyg X-1, was monitored between July and December 1975 from the Spanish Sierra Nevada. The data are shown in Fig. 2, and are compared with the X-ray behaviour of Cyg X-1 as measured by Copernicus and inferred from the Ariel V and ANS data reported in refs 2 and 3. The crosses represent nightly mean blue magnitudes and have a typical standard error of $\pm 0.003 m_B$.

We note, first, that the mean B-band flux reaches a local maximum close to the time of the X-ray transition. This may be coincidental, however, since such maxima are not unprecedented and have not previously been correlated with any known X-ray event. Of more significance is the detailed form of the blue light curve about the time of the X-ray transition. As observed in previous years, the average blue light curve

for the 1975 data is typified by a distorted double sine wave per orbital period[6–8]. To quantify the light curve distortion, we have fitted a double sine wave to the individual three-orbit intervals marked in Fig. 2, allowing the amplitude and mean magnitude to vary so as to minimise χ^2. The phase of the double sine wave was taken to be the mean phase obtained by fitting all of the 1975 data.

The best-fit parameters and the corresponding reduced χ^2 for each interval are shown in Table 1 and light curves for the intervals about the time of the X-ray transition are shown in Fig. 3. The data points and the best-fit double sine wave for interval E are shown in Fig. 3*a*. This light curve is typical of the data from July to October 1975, and the large values of χ^2 for intervals A to E indicate the relatively large departures from a double-sine-wave light curve.

A change in the character of the light curve was observed, starting on the night of 25/26 October, as shown in Fig. 3*b*. On this night the B-band flux was abnormally faint, and then increased to an abnormally high value two nights later. No light variations were then seen over the following three nights.
Fig. 2 *a*, Blue-band magnitude of HDE226868 from July 1975. The filled circles represent means (uncertainty $\sim 0.004 m_B$) over the intervals marked (~ 3 orbits). The X-ray flux from the present work (——) and from refs 3 and 4 (— —) are shown in *b*. Times of superior conjunction of the X-ray source are indicated on the abscissae.

During the interval immediately after the X-ray turn-on, regular light variations were again observed, as indicated in Fig. 3*c*, which shows data and the best-fit double sine wave for interval F. The degree of departure from the best-fit curve was, however, considerably reduced, as demonstrated by the low value of χ^2 for this interval. (Note that the six data points shown in Fig. 3*b* are not included in interval F.) Distortion of
Fig. 3 *a* and *c*, Blue-band data folded with the 5.6-d orbital period. *b*, Data (unfolded) for the 6 d spanning the transition in X-ray flux noted in the text. Formal errors of measurement are $\pm 0.003 m_B$. The best-fit double sine curves are indicated for the data in *a* and *c*. The best-fit curve to the data shown in *c* is superimposed on the unfolded data in *b*, for reference. *a* (Interval E), JD 2442684–698; *b*, JD 2442711–716; *c* (Interval F), JD 2442717–736.

the light curve became more pronounced again towards the end of the 1975 data, as indicated by the higher value of χ^2 for interval G. It is important to note that the behaviour described above is unprecedented in a total of 400 nights of optical monitoring of the source distributed through the past 4 yr.

As the unique change in the optical behaviour of HDE226868 coincides to within one orbital period with the onset of the transition of Cyg X-1 to its high state, it is highly probable that the X-ray and optical events are related. Our immediate conclusion is that the optical variability is influenced by the condition of the X-ray source, and if ellipsoidal-like variations, as discussed by Hutchings[9] and Avni and Bahcall[10], do occur, then at times they are insignificant by comparison with this other mechanism.

Suspected globular clusters in the Fornax I cluster of galaxies

HERE we report the existence of a significant clustering of faint objects around three galaxies in the Fornax I cluster of galaxies. The nature of these objects is uncertain, although on the scant evidence available, we believe at least some of them to be unresolved globular clusters. We base our claim on the examination of a single, direct photographic plate taken by Dr R. D. Cannon at the prime focus of the Anglo–Australian telescope on the night of January 18, 1975. The plate, AAT609, is an unsensitised IIaO, exposed for 20 min through a GG 385 filter, and covers an area of $1° \times 1°$ centred on RA 3 h 36 min, dec. $-35.5°$ (1950.0). The smallest images on the plate are slightly elliptical, owing to slight trailing in RA, and have dimensions $1.5'' \times 2.0''$. In the course of assigning morphological types to the brightest galaxies in the field, we found a noticeable increase in the number of faint objects in the vicinity of the galaxies NGC1374, NGC1379 and NGC1399. These three galaxies are all elliptical and are among the nine brightest on the plate. Of the remaining six bright galaxies, two (NGC1389 and NGC1404) are elliptical and four (NGC1375, NGC1380, NGC1381 and NGC1387) are lenticular; none of these six galaxies exhibits any significant enhancement in the number of adjacent field objects.

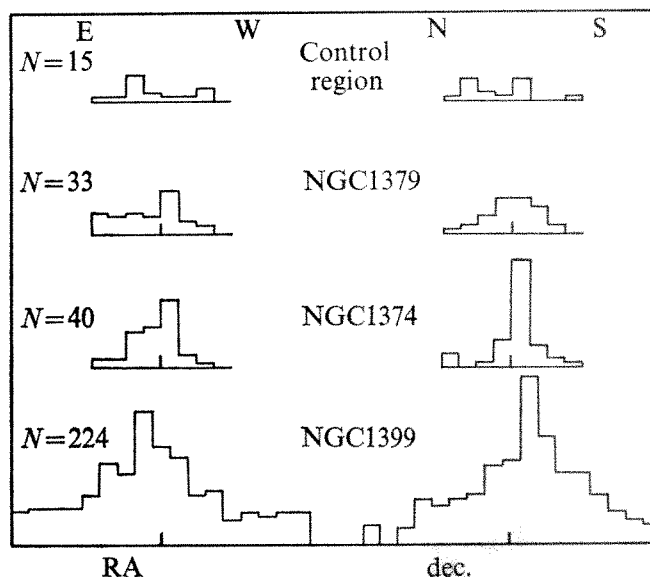
In Fig. 1, we show the marginal distributions in RA and dec. of the faint objects around the three galaxies, and in


Fig. 1 Marginal distributions of faint objects around three galaxies in Fornax I, and in a control region. The ordinates are in the same arbitary units for all the histograms. N represents the total number of faint objects in each area measured. The widths of the histograms for NGC1399 are both 10.7', those for the remaining regions are 5.0'.

a control area centred on a star at RA 3 h 34 min, dec. $-35.3°$, well removed from any bright galaxy. The counts were made visually with the aid of a low-powered microscope and a rectangular grid (of unit size $18.9'' \times 18.9''$ on the plate), and the positions of all objects were recorded. The area measured round NGC1399, the brightest of the three galaxies, was $10.7' \times 10.7'$, whereas the corresponding areas for the other two galaxies and the control region were $5.0' \times 5.0'$. Those objects judged to be faint were selected solely on the criterion of image size and not of image structure. They were estimated to be within 1 mag of the limiting magnitude of the plate. In all, 224 were found around NGC1399, 40 around NGC1374 and 33 around NGC1379. For comparison, the number of faint objects in the control region was 15.

The density distribution of faint objects around NGC1399, derived from ring counts (Fig. 2) has been fitted with a truncated isothermal distribution assuming spherical symmetry. The asymptotic value of the density of $3.4 \times 10^3 \pm 1.4 \times 10^3$ (s.e.) per degree^2 is slightly higher than the density of 2.2×10^3 per degree^2 found in the control region. In view of the differences in the dispersion of the marginal distributions in RA and dec. (Fig. 1), we thought it necessary to check the assumption of spherical symmetry. We have fitted the observations with a bivariate Gaussian distribution and found major and minor axes of $154''$ and $133''$ (that is, an ellipticity of 0.13), and that the position angle of the major axis is $105°$. This weakly confirms the impression given to the eye that the cluster of faint objects around NGC1399 is slightly elongated in the direction of the major axis of the galaxy (position angle $115°$). The centroid of the distribution however, lies $28''$ to the SE of the centre of NGC1399, and there is a relative paucity of objects in the NE sector of the galaxy. The NGC1374 system seems symmetrical and well defined. The smaller number of objects around NGC1379 inhibits any assessment of the symmetry of the distribution.

The average density of all stellar images on the plate is 4×10^3 deg^{-2}. If we tentatively identify these with foreground stars within our Galaxy, then we may extrapolate an approximate value for the limiting magnitude of the plate from tables of star numbers given by Allen[1] (with the appropriate correction for magnitude scale errors given by
Fig. 2 The radial density distribution (number arc min^{-2}) of the faint objects around NGC1399 (dots, with corresponding error bars). The best isothermal fit is shown by the continuous curve.

Arp[7]). For the galactic latitude of Fornax I, $b^{\text{II}} \sim -54°$, the above density corresponds to a limiting B magnitude of 22.5±1.5 mag (estimated error). Although plate AAT609 was not calibrated, another estimate of its limiting magnitude may be obtained from a comparison with plate AAT610 taken on the same night. This is a B plate of NGC288, which contains a standard photoelectric sequence (R. D. Cannon, personal communication), and has a limiting magnitude of 21.6±0.5 mag (±s.e.). Allowing for slight differences in exposure times ($\Delta m = -0.4$ mag), air masses ($\Delta m = +0.2$ mag) and seeing ($\Delta m = +0.2$ mag), we conclude that an appropriate average value for the limiting magnitude of AAT609 is 22.0±0.5 mag (±s.e.).

The corrected redshift of Fornax I (ref. 3) is $z=0.0050\pm 0.0003$ (±s.e.) and, if $H=55$ km s^{-1} Mpc^{-1}, this corresponds to a provisional distance of 27 Mpc. If the faintest of the suspect objects is characterised by an angular size of less than 2″ and an apparent B magnitude of 22.0 mag, then at this distance these parameters correspond to a linear dimension of less than 260 pc and an absolute B magnitude of about −10 mag. We suggest that these objects are unresolved globular clusters, although there are some difficulties associated with this hypothesis, which we discuss below.

The existence of globular clusters around a number of galaxies in the Virgo cluster[4,5] and, in particular, around the active elliptical M87 invites a comparison. Racine[4] has analysed the distribution of 2,000 globular clusters around M87 and more recently Hanes[5] has studied globulars associated with twenty galaxies (including M87) in the Virgo cluster. Hanes (personal communication) has revised Racine's conclusions regarding the luminosity function of the M87 globulars. He finds that there is no sharp cutoff at the bright end of the luminosity function, but rather a Gaussian tail with the brightest globular occurring at about $B=20.4$ mag The brightest of the Fornax objects lies at about 1 mag above the plate limit and has an apparent

B magnitude of 21.0±0.6 mag. The hypothesis that the upper limit to globular luminosities, around any given galaxy, is set by statistical fluctuations in random samples of various sizes, has been used by de Vaucouleurs[7] to substantiate an empirical linear correlation between the absolute magnitude of the first-ranked globular and the total absolute magnitude of the associated galaxy. We have used this correlation to obtain corrected distance moduli for M87 and NGC1399 of 30.4 mag and 30.8 mag respectively (allowing for 0.2 mag of extinction in both cases) and absolute magnitudes of the two galaxies of −21.1 mag and −20.2 mag for the corrected B magnitudes of 9.35 mag and 10.62 mag (ref. 8). The corresponding absolute B magnitudes of the brightest globulars in the two systems are at −10.0 mag and −9.8 mag. M87 has, however, been suspected to be abnormally rich in globular clusters (D. A. Hanes, personal communication) and a more detailed calculation will be presented later (de Vaucouleurs and J. A. D., unpublished). The difference in the distance moduli of M87 and NGC1399 is 0.4 mag, which corresponds to a distance ratio of 1.20. This may be compared with the ratio of the corrected redshifts[3] for the E cores of Fornax I and Virgo, which equals 1.45.

Fornax I lies within the Southern Supercluster which stretches from Cetus to Dorado[9]. The background density of faint galaxies is high and non-uniform, and the possibility that the clusters of faint objects around the three galaxies might result from chance alignments must be considered. This possibility is supported by the observation that there are few faint objects around NGC1404, even though it is a galaxy of similar luminosity to NGC1399. Although the system around NGC1399 is the most populous and extensive, the marked asymmetry of the distribution about the galaxy must raise doubts as to whether the two are physically related. Indeed, a Coma-like cluster of galaxies, removed to forty times the distance of the Coma cluster, would match the distribution both in angular extent and apparent magnitude of the 10th-ranked member. The number of objects around NGC1379 is sufficiently small to be accounted for as a local enhancement in the number of field objects, but in NGC1374 there is a system which gives the firm impression of a symmetrically placed distribution of globular clusters.

Smith and Weedman[10] have reported the discovery of globular clusters around NGC3311 in the Hydra I cluster of galaxies and, in common with others[4,6,7], have discussed their use as distance indicators leading to an evaluation of the Hubble constant. Fornax I is about 150° away from the supergalactic centre in Virgo and is well placed to reflect any apparent anisotropy in the Hubble flow which may arise from systematic motions within the local supercluster.

We thank Professor G. de Vaucouleurs, Dr M. G. Smith and the staff of ROE for helpful discussions, Dr H. A. Hanes for communicating his unpublished data and for many constructive suggestions, and also Dr R. D. Cannon for the loan of plate AAT609.

Night-time reception of a solar radio event

ON March 30, 1976, at 2104–2106 UT, anomalous high-level radio bursts were recorded with a 48-channel polarised high resolution radio spectrograph[1] operating at a frequency range of 20.85–23.20 MHz. The observation was made at Kiiminki (65°05′N, 25°54′E), in the complete absence of interference of any kind and with the Sun and Jupiter well below the horizon. The antenna (two crossed log-periodic units in parallel) was directed towards North and elevated 30° for the purpose of recording scintillation spectra of the radio source Cassiopeia A. The spectrograph is designed primarily for observations of Jupiter[2] and its sensitivity for recording Cassiopeia A is marginal.

The anomalous bursts are shown in Fig. 1. The power level of the bursts exceeds the highest scintillation peaks of Cassiopeia A by 10–15 dB. The level is comparable to

Fig. 1 Dynamic spectra of anomalous night-time radio bursts.

that of the strongest Jovian bursts observed close to the opposition of the planet. The colour[1,2] of the original record indicates that the right- and left-circular components of the emission had equal amplitudes.

At the same time, a strong solar radio event was in progress. From the radio spectra obtained at the CSIRO Solar Observatory, Culgoora, Australia; at the Harvard Radio Astronomy Station, Fort Davis, Texas (see Fig. 2); and at the Department of Astro-Geophysics, University of Colorado, Boulder, Colorado, it is inferred that the bursts are of solar type III. As can be seen from Fig. 2, the bursts start in the vicinity of 80 MHz. At the lowest recorded frequency (25 MHz) they match well with the bursts shown in Fig. 1.

Anomalous propagation of solar bursts have been observed previously[3]. In the present case the bursts must have been guided from the sunlit hemisphere over the polar regions. It may be significant that on the night of March 30, an auroral substorm and a strong blanketing sporadic-E (E_s) were observed (ref. 4 and T. Turunen, personal communication). A suitable duct may have existed between the ground and the E_s layer. This assumption is supported by

Fig. 2 The corresponding record of solar radio bursts, obtained at Fort Davis, Texas.
the low attenuation of the bursts. From their estimated flux density (A. Maxwell, personal communication) it is deduced that the total attenuation was less than 10 dB, probably just a few dB. The waves first penetrated the F2 layer, perhaps at a relatively high latitude, and then entered the duct beneath the E_s layer, provided the latter extended far enough towards the sunlit hemisphere.

The event was also recorded with a 20-MHz riometer at the Sodankylä Geophysical Observatory (67°25′N, 26°24′E). It appears as an outstanding peak signifying an increase in the noise level. It was not detected with the 27.6-MHz riometers at Sodankylä or at stations elsewhere in Finland (H. Ranta, personal communication) although strong solar emission occurred also at this frequency.

I thank Drs A. Maxwell, G. A. Dulk, and K. V. Sheridan for the Fort Davis, Boulder, and Culgoora solar records, and Mrs H. Ranta and Mr T. Turunen for the Sodankylä riometer and ionospheric data.

Absorption and the low velocity zone

IT is well known that elastic wave velocities are independent of frequency only for a non-dissipative medium[1]. In a real solid dispersion must accompany absorption. This effect has been emphasised by Randall[2] and Liu et al.[3]. The effect is small when the seismic quality factor Q is large or unimportant if only a small range of frequencies is being considered—that is, the spectra of P waves. Even in these cases, however, the measured velocities, or inferred elastic constants, are not the true elastic properties but lie between the high frequency and low frequency limits or the so-called 'unrelaxed' and 'relaxed' moduli. The magnitude of the effect depends on the nature of the absorption band and the value of Q. When comparing data taken over a wide frequency band the effect of absorption can be considerable especially considering the accuracy of present body-wave and free-oscillation data. Thus, Jeffreys[4] questions conclusions based on free oscillation data, particularly where they differ from body-wave results which are based on much shorter periods. Carpenter and Davies[5] and Davies[6] attempted to reconcile body-wave and surface-wave Earth models by allowing for physical dispersion using Futterman's[7] and Kolsky's[8] dispersion–absorption relationships. Jeffreys[4] used Lomnitz'[9] relationships. Liu et al. have shown that dispersion depends to first-order on absorption in the seismic frequency band and derived a linear superposition model that gives a Q that is independent of frequency. It can be shown that all of the above theories give equivalent absorption–dispersion relations for moderate absorption. Liu et al.[3] and Anderson et al.[10] have shown how to correct surface-wave and free-oscillation data for physical dispersion. Much of the support for the existence of an upper mantle low velocity zone has come from the inversion of normal mode data that have been uncorrected for physical dispersion due to absorption. In the light of these developments, we decided to re-examine the question of a shear-wave low velocity zone.

A starting model was constructed with monotonically increasing velocity and density in the upper 400 km of the mantle. The P and S velocities were chosen to satisfy the Jeffreys–Bullen[11] travel time tables to 30°. A smooth, Bullen[12] model A, density structure was used for this region. The model has a 3-km thick ocean layer, and an 18-km thick crustal layer.
V_s (km s^{-1})

Fig 1 Shear velocity (V_s) as a function of depth for the starting model (dashed) and final model (solid).

These are average values for the Earth[13]. Below 400 km the parameters are the same as model C2 of Anderson and Hart[13].

Following Anderson et al.[10], the observed eigenperiods were corrected for the effect of absorption. A reference period of 1 s was selected to enable comparison with body-wave results. The corrected data included 66 fundamental spheroidal modes, 46 fundamental toroidal modes, 10 spheroidal overtones and 80 toroidal overtones. The spheroidal modes were selected for their sensitivity to shear velocity. The Q model MM8 of Anderson et al.[14] was used to compute the correction. This data set was then inverted, following the technique described by Jordan and Anderson[15]. The shortest smooth perturbation from the starting model which satisfies the data is found by this procedure.

The starting model does not provide a satisfactory fit to the normal mode data. The r.m.s. error is 0.7% whereas the r.m.s. error of the data is 0.09%. Only three modes are fit to within 1 s.d. of the data, and the errors for the shorter fundamental spheroidal modes (Rayleigh waves) are as large as 1.9%. The final model fits the data with an r.m.s. error of 0.07%; of the representative 78 modes used in the inversion, 62% fit the data to 1σ and 95% fit to 2σ.

The resulting upper mantle shear velocity (solid line) is shown in Fig. 1, together with the starting model. The new model has a pronounced low velocity zone with shear velocity decreasing from 4.77 km s^{-1} at the top of the mantle to a minimum of 4.42 km s^{-1} at 170 km. The average JB shear-wave travel time residual for the new model is +0.05 s over the distance range 30–95°. This can be compared with the 4–6-s discrepancy found from previous studies in which absorption was ignored[13,15].

We agree with Jeffreys[4], Davies[6], and Carpenter and Davies[5] that absorption must be taken into account when inverting surface-wave and free-oscillation data. Although some important revisions are required to Earth models determined from previous studies[13,15] we conclude that a low velocity zone is required by the observed data. There is no longer any 'baseline' discrepancy between body waves and normal modes. A more complete inversion which utilises the complete spheroidal mode data set will be reported elsewhere.

Effect of nearby supernova explosions on atmospheric ozone

WE have calculated the probable effects of a nearby supernova event on the ozone layer. We find that the effects are significant and long lasting, but are relatively rare at the location of the Earth in the Galaxy.

Ruderman[1] has suggested that cosmic-ray particles and γ rays produced by a nearby supernova could cause a substantial depletion of the Earth's ozone shield, with a consequently strong increase in the solar ultraviolet radiation incident on the surface of the Earth.

The suggested mechanism for ozone destruction is the formation by incident ionising radiation of large quantities of nitrogen oxide (NO_x) in the stratosphere. The NO_x then catalytically converts the ozone (and atomic oxygen) to molecular oxygen through the reaction sequence

$$NO + O_3 \rightarrow NO_2 + O_2 \text{ and } NO_2 + O \rightarrow NO + O_2$$
Ruderman has estimated the reduction in ozone column density that would result from a 10^{47}–10^{48}-erg burst of γ rays with a duration similar to that of a visible supernova event, that is, short compared with the residence time of NO_x in the stratosphere. He has also estimated the reduction that would result from an extended 'pulse' of cosmic rays with a total energy of ~ 10^{50}–10^{51} erg and a duration[2] of ~ 100 yr, the characteristic diffusion time over the distance from the supernova. The reductions obtained are quite dramatic; up to 90% in the case of the γ-ray burst.

We have applied more recent astronomical observations and somewhat different astrophysical concepts to the calculation of the intensity of ionising radiation expected from a supernova event. More refined models[3] of atmospheric chemistry and transport have been used to calculate the ozone depletion attributable to NO_x catalysis. We conclude that the ozone depletion, although smaller than that estimated by Ruderman, is still significant, and could, as a result of cosmic rays, extend over a very long period of time (10^3–10^4 yr); however, the probability of such an occurrence within the past 10^8 yr seems to be low.

In calculating the effect of γ rays, we first considered the possibility, as did Ruderman, that observed pulses of γ rays

in the 1–500-keV range[4] are attributable to extragalactic supernovae. This gives an upper limit on the energy content of a supernova γ-ray pulse of 10^{47}–10^{48} erg. Following Ruderman, we assume that all of the incident energy deposited at an altitude of 25–35 km. Our model enables us to follow the dynamics of the response of the atmosphere to a pulse, which we took to be a square wave of duration equal to the duration of the optical event (~ 100 d). Our calculations show that the occurrence of such an event 10 pc from Earth would result in peak ozone-column reduction of 35–65% for the 10^{47} and 10^{48} erg (upper limit) pulses, respectively. Such values are smaller than, but comparable to, Ruderman's estimates. As the e-folding recovery time of the stratosphere (the stratospheric residence time of NO_x) is ~ 3 yr, the time for the atmosphere to recover to 95% of normal would be ~ 10 yr.

Direct observations[5,6] of supernovae before, during, and after optical maximum give an upper limit to the emitted power in the 1–500-keV range of 10^{41} erg s^{-1}, which is compatible with the 10^{47}–10^{48} erg assumption discussed previously. Recent searches for smaller bursts[7] seem, however, to favour the hypothesis of galactic origin, reducing the estimated intrinsic burst energy by a factor $\sim 10^6$. Such an energy would be completely insignificant with respect to ozone reduction.

In previous calculations of the terrestrial effects of the cosmic rays produced by nearby supernova events, such as those by Ruderman[1] or by Laster[2], it has been assumed that the explosion accelerates a substantial fraction of the envelope to relativistic velocities, producing a 'pulse' of cosmic rays of energy comparable in magnitude to the total energy of the event (10^{50}–10^{51} erg). Recent spectroscopic observations suggest, however, that this is not the case[8], and tend to support models of the outburst which do not predict cosmic-ray 'pulses' of any significant energy[9]. It is known, however, that supernova remnants (SNR) expanding into the interstellar medium contain trapped cosmic-ray particles of high energy. The total energy content of SNRs can be deduced from the observed synchrotron radiation from trapped electrons. Our approach, then, is to assess the effects of envelopment of a planet in an expanding SNR containing trapped cosmic rays. The effects of such radiation would persist for the lifetime of the SNR ($\sim 10^3$–10^4 yr) and would be expected to be more biologically significant than a 10–10^2-yr effect of comparable magnitude.

To estimate the total energy contained in the form of trapped cosmic rays, W_{cr}, we have taken values of W_{cr} given by Ginsburg and Syrovatskii[10] for eight remnants with radii between 2 and 20 pc, and corrected them using more recently determined radii[11]. It seems that W_{cr} remains roughly constant over the lifetime of SNRs, at least in this size and age range, with a value of $W_{cr} \sim 2 \times 10^{49}$ erg. Assuming that the particle energy density decreases as r_0^{-3}, where r_0 is the radius of the SNR, and assuming also an isotropic particle velocity distribution with $|v| \sim c$, the intensity of cosmic radiation ($E \gtrsim 100$ MeV) at a point within the SNR is $\sim 10^{10}/r_0^3$ erg cm^{-2} sr^{-1} yr^{-1}, where r_0 is in parsec. We choose $E = 100$ MeV as a low-energy cutoff because cosmic-ray particles of energies greater than ~ 100 MeV are not deflected appreciably by the interplanetary magnetic field associated with the solar wind. The calculated intensity would then represent an increase over the current background level[12] of a factor of 10^2 for $r_0 \sim 10$ pc and about 10^3 for $r_0 \sim 5$ pc. Because of the lower initial energy we used, enhancements (an enhancement of 1 implies a doubling of the background level) are less than those calculated by Ruderman[1], but the duration of the exposure of a planet in the situation treated here would be about the lifetime of the SNR, $\sim 10^4$ yr, as opposed to the $\lesssim 10^2$ yr duration of an hypothetical 'pulse' of cosmic rays. In addition, significantly greater enhancements over shorter periods may be expected in the case treated here, because of the non-uniform distribution of particles within the SNR (for example, 'whisps' in the Crab and Cygnus or 'knots' in Cas A[13]).

The model calculations of atmospheric effects correspond to the steady state in this case, because the duration of the event is
Fig. 1   Reduction (%) of ozone column density in the steady state as a function of the cosmic-ray enhancement factor.

very long compared to the stratospheric recovery time. The calculated global ozone reductions for various cosmic-ray enhancements up to a factor of 10^3 are shown in Fig. 1. It is seen that ozone reductions of ~ 20–50% could be expected from enhancements of 10^2–10^3. Although these reductions are smaller than estimated by Ruderman[7], they are still considerable, especially in the light of their probable long duration.

The waiting time, T_w, for a supernova outburst to occur within a volume $V_0 = (4\pi/3)r_0^3$ of the Galaxy is given by $T_w = T_{Gal}V_{Gal}/V_0$, where T_{Gal} is the galactic average time between supernovae in a total volume V_{Gal}. The distribution of supernovae in our Galaxy in space and time is still a matter of some uncertainty. Within 8 kpc of the galactic centre, SNRs seem to lie within a disk ~ 120 pc thick, and from 8 to 14 kpc the thickness is perhaps twice as large and the total volume density is $\sim 1/4$ as great as in the inner regions[11]. Using these observations and a mean time between supernova events of $T_{Gal} = 50$ yr, consistent with optical, SNR, and pulsar observations[14–17], we have found that at the location of the Earth (10 kpc from the galactic centre), waiting times for extended ($\sim 10^4$ yr duration) ozone depletions of 20–50% are between $\sim 2 \times 10^9$ and $\sim 2 \times 10^{10}$ yr. The probability that such an event occurred near (that is, ~ 5–10 pc from) the Earth within the past 10^8 yr is ~ 1–5%. Interestingly, the waiting times for such events to occur near a given planet at less than 8 kpc from the galactic centre are much shorter, $\sim 10^8$ and 10^9 yr, respectively.

It thus seems that the ozone depletion effect is significant and long lasting, and may affect the surface biology of the Earth or any Earth-like planet greatly, but is of low probability in our region of the Galaxy. Considering that cosmic and γ radiation does not penetrate to the surface in sufficient doses to affect life in a direct sense[1], and that ultraviolet light from a supernova at several pc is weaker than that from the Sun and of short duration (< 1 yr), the calculated ozone depletion would seem to be the major effect of a supernova on a nearby (~ 5–10 pc distant) Earth-like planet.

Heavy-ion damage in α Fe

WE summarise here some preliminary observations of damage in α Fe irradiated with low doses of heavy ions at room temperature. Although the damage produced by such irradiation has been studied in a number of pure metals and alloys using transmission electron microscopy[1], there have been comparatively few studies of materials of technological interest. Iron is of particular interest since it is a major constituent in many practically important alloys including ferritic steels. The use of heavy-ion irradiation (typically to doses $\lesssim 10^{13}$ ions cm^{-2} and energy $\lesssim 200$ keV) provides a convenient method of simulating the displacement cascades generated in metals undergoing fast neutron irradiation. In a majority of the metals and alloys studied the damage consists of a population of vacancy loops produced heterogeneously at the cascade sites by a collapse of the vacancy-rich cascade centres. Interstitial loops are not normally observed at the low doses commonly used, and this is thought to result from the close proximity of the damage region to the foil surface (the mean range of ions is typically ~ 100 Å) which acts as a dominant sink for the mobile interstitial point defects. There have been no previous reports of low-dose heavy-ion damage in α Fe and in other damage experiments[2] the vacancy component of the damage was not observed.

In this experiment, thin polycrystalline foils of α Fe were irradiated at room temperature with heavy ions of energy between 40 and 240 keV to doses $\simeq 5 \times 10^{12}$ ions cm^{-2}. The ions used were Fe$^+$, Ni$^+$, Ge$^+$, Kr$^+$, Xe$^+$ and W$^+$, with atomic weights ranging between 56 and 184. The iron used was the same material as that used in ref. 3 where the method of preparation of the specimens and an analysis of the iron purity is given. After irradiation, the foils were examined in a Siemens 102 or a JEM 100B electron microscope. A major experimental difficulty was the appreciable growth of oxide film, even though the specimens were stored under high vacuum (10^{-5} mmHg) after thinning. This, together with problems in producing foils with smooth surfaces and in completely eliminating objective astigmatism, meant that image quality was not as good as can be obtained in other materials. We estimate the visibility threshold for small loops in the best foils to be ~ 20 Å.

A detailed analysis of dynamical black–white images in foils irradiated with 80 keV W$^+$ ions has revealed the presence of two kinds of perfect loops with a/2 ⟨111⟩ or a ⟨100⟩ Burgers vectors. All the loops were of vacancy type. The results are consistent with the sequence proposed for the nucleation of interstitial loops[4]: aggregation initially on [110] followed by shear to a/2 ⟨111⟩ or a ⟨100⟩. The relative numbers of the two kinds of loops appear to depend sensitively on the grain orientation. A full analysis of these results will be reported later.

Information on cascade collapse in α Fe has been obtained from measurements of the efficiency with which various ions produce visible clusters. Results for different 80 keV ions are shown in Fig. 1, where the defect yield (defined as the fraction
Fig. 1 Plot of defect yield against ion mass for grains close to ⟨110⟩ bombarded with 5×10^{12} 80-keV ions cm^{-2}.

of cascades which collapse to produce visible clusters) is plotted as a function of the ion mass. No correction has been made for loops slipping out of the foil, but care was taken that grains of similar orientation (in this case near ⟨110⟩) were selected for defect counting. The relative values of the defect yield should, therefore, be meaningful. Figure 1 illustrates two important results. Firstly, self-ions produce no visible damage; this was true for all ion energies in the range 40–240 keV. Secondly, the defect yield is a strong function of the mass of the incident ions, increasing from zero for Fe$^+$ ions to ~ 20% for W$^+$ ions, the heaviest ions investigated. The loops in α Fe irradiated with 80-keV W$^+$ ions ranged in size up to ~ 100 Å, but most were much smaller than this, ~ 90% falling in the size range 20–50 Å.

The absence of observable damage in self-ion irradiated specimens is consistent with results from neutron-irradiated α Fe[2] which showed that no visible damage is produced at doses $\lesssim 5 \times 10^{18}$ cm^{-2}. This suggests that cascades initiated by self-ions do not collapse, at least at room temperature and above. If this is so, it could have important consequences on the void swelling characteristics of α Fe, as have been discussed in ref. 5.

The explanation for the second observation concerning the sensitivity of the defect yield to ion mass cannot lie in differences in the total number of displacements produced, since, according to calculations[6], the ions used all produce approximately the same number of displacements, ~ 500 for 80 keV ions (the calculated numbers are shown in Table 1). What does alter, however, is both the spatial distribution of the damage and its depth below the foil surface. We do not consider that the latter affects the cascade collapse. Thus with increasing ion mass cascades become more compact, the vacancy supersaturation is higher and the cascade is hotter (in the sense that the density of energy deposited is increased). The magnitude of the effect is shown in Table 1. The quantities $\langle \Delta X^2{}_D \rangle$ and $\langle Y^2{}_D \rangle$ are related to the second moments of the energy distribution function and give measures of the cascade radius parallel and perpendicular to the incident ion direction respectively, while $\langle X_D \rangle$ gives a measure of the mean depth of the damage. These quantities have been computed from the WSS analytical theory[7]; θ_0 is an estimate of the maximum energy density in the cascade, calculated from ref. 8. In going from Fe$^+$ to W$^+$

Table 1 Calculations on collision cascades created by 80-keV ions

Ion	Fe	Ge	Kr	Xe	W
Atomic mass	56	76	84	131	184
No. of vacancies in cascade	507	513	518	535	548
$\langle X_D \rangle$ (Å)	193	169	156	105	95
$\langle \Delta X^2{}_D \rangle^{1/2}$ (Å)	120	102	96	64	59
$\langle Y^2{}_D \rangle^{1/2}$ (Å)	77	65	60	44	40
θ_0 (eV per atom)	0.21	0.37	0.42	1.26	1.81

ions the volume of the cascade decreases by about an order of magnitude, and the maximum density of deposited energy increases by about the same factor.

The work of English *et al.*[5] and English (unpublished), has highlighted the difficulty of cascade collapse in another b.c.c. metal, molybdenum. It was found that the defect yield produced by heavy-ion bombardment was dependent on both the irradiation temperature and on the mass of the incident ions. For 60-keV Mo[+] ions the defect density decreased at irradiation temperatures > 200 °C. This decrease cannot be explained on a vacancy-emission mechanism, where cascades are assumed to collapse athermally and then shrink by vacancy emission, nor by loop loss to the surface. The former mechanism had been successful in explaining the decrease in defect density in copper irradiated at high temperatures with 30-keV Cu[+] ions[10]. It seems that in self-ion irradiation of molybdenum the collapse process is itself temperature dependent. Further experiments with 60-keV Xe[+] and W[+] ions have, however, shown that the defect density in these cases remains unchanged at temperatures up to 425 °C, the highest irradiation temperature which could be achieved. It would seem, therefore, that in b.c.c. materials there is a sensitive balance between the collapse of vacancies in a cascade to a vacancy loop or their retaining an uncollapsed distribution and perhaps dispersing in the lattice.

Our results suggest that an important parameter in determining whether or not cascade collapse occurs in α Fe is the energy density or compactness of the cascades. The results from Mo irradiated with heavy ions at high temperatures provide further support for this concept and also suggest that an important and closely associated factor could be the rate at which vacancies diffuse out of the cascade centre into the surrounding crystal. There is considerable doubt regarding the temperature range for long range vacancy migration in α Fe and thus we are not able to separate this factor from the energy density factor in the present results. We plan to clarify this by irradiating iron specimens with ions of different masses at 77 K. The results from pure f.c.c. metals and alloys suggest that energy density in the cascade is a less critical factor governing cascade collapse than for b.c.c. metals. Nevertheless, there is a marked trend for higher cascade collapse efficiencies on going to heavy metals irradiated with self ions, Cu/Cu[+] → Ag/Ag[+] → Au/Au[+]. Moreover, Häussermann[11] has shown that in ion-irradiated copper the efficiency of cascade collapse to vacancy loops is higher for Au[+] ions that for Cu[+] ions, while Ruault *et al.*[12] have shown that in ion-irradiated gold the nature of the collapsed defects is also a function of ion mass. It seems, therefore, that energy density and cascade compactness are important parameters governing the development of damage structures in irradiated metals and their influence needs to be better understood.

Mechanical forces of electromagnetic origin

EXPERIMENTS have been reported which verified that at low frequencies a time-varying polarisation P in a dielectric, if taking place in a magnetic field H, results in a mechanical force of density $\dot{P} \times \mu_0 H$. This force is not predicted by the Minkowski energy momentum tensor, but the Abraham form of that tensor gives a force density in an homogeneous isotropic body of magnitude

$$[(\varepsilon_r \mu_r - 1)/c^2]\, \frac{\partial}{\partial_t}(E \times H)$$

usually called the 'Abraham Force'. In a dielectric this can be written $\dot{P} \times \mu_0 H + P \times \mu_0 \dot{H}$. It is not surprising that $\dot{P} \times \mu_0 H$ should give a mechanical force, since P corresponds to a movement of electric charge associated with polarisation, but it is difficult to understand why $P \times \mu_0 H$ should give a force.

To try to obtain experimental evidence of this effect, the same equipment was used as previously[1,2], namely a disk of barium titanate suspended as a torsional pendulum between the poles of a powerful electromagnet, the only change from the previous experiment was to hold P fixed but to vary H with time at the same frequency as the oscillation of the disk. Great difficulties were caused by the magnet system. A considerable coupling of energy to the pendulum resulted from mechanical vibrations in the magnet coils and there may also have been electromagnetic coupling because of small geometrical imperfections in the system. To avoid such resonance effects, we devised the following procedure.

If E and H have the same frequency, then, irrespective of their phase relationship, the time average of the Abraham Force is always zero. Thus if E and H are in time quadrature and if in fact $P \times \mu_0 H$ produces no mechanical force, there should be a time-averaged unidirectional force given by $\dot{P} \times \mu_0 H$. In the experiment, E and H were in time quadrature but at a frequency about 250 times the resonant frequency of the pendulum, thereby avoiding parasitic coupling from the magnet system. It was arranged that the direction of the electric field applied across the disk was reversed at the instants when the torsional pendulum reversed in its direction of motion, thereby ensuring that the applied force (if any) would always assist the oscillation of the pendulum. If no oscillation beyond the noise level resulted, the Abraham Force would be verified. In fact, a strong oscillation was observed which agreed closely (within 4%) with the amplitude predicted by the term $\dot{P} \times \mu_0 H$ acting alone.

Full details will be published elsewhere, but we conclude that neither the Minkowski tensor nor the Abraham tensor is consistent with the observed effects.

High resolution image of copper phthalocyanine

WE report here the successful high resolution of organic material by electron microscopy, a technique extremely sensitive to electron irradiation. As is well known, an inevitable factor that limits such high resolution microscopy is severe radiation damage, and, therefore, the electron beam must be reduced very much below the critical dose to prevent higher order details from fading. As a result, one cannot get high contrast
Fig. 1 Thin film for observation was prepared by vacuum deposition on a freshly cleaved KCl substrate, which had been preheated at 400 °C for 1 h. Film thickness was controlled carefully to be < 100 Å. We regard it as a perfect phase object. *a*, High resolution electron micrograph viewed along the *b* axis. Careful inspection reveals some crystal details. *b*, The relationship of the molecular orientation between the averaged imaged and the assumed isomorphic structure. $X_R X_R'$ indicates the molecular orientation of the retrieved image, $X_0 X_0'$ the assumed molecular orientation. *c*, The averaged image obtained by using the redundancy information from an enclosed region, by an optical method ($\times 1.24$).

by using the usual films, and we used an X-ray film (Ilford, Industrial G) with a high quantum efficiency. With this film, the exposure time did not exceed 5–7 s in conditions of minimal beam irradiation (Williams *et al.*[1]).

The specimen used was copper phthalocyanine, a widely used pigment. The thin film specimen for observation was grown epitaxially on a substrate of KCl. Preliminary experiments have found its crystal structure to be of the metastable α form[2], with crystal parameters: $a = 2.592$ nm, $b = 0.379$ nm, $c = 2.392$ nm, $\beta = 90.4°$, monoclinic, C2/c. Furthermore, its crystal structure was found by Ashida[3] to be closely isomorphic with platinum phthalocyanine (Robertson *et al.*[4]). The epitaxially grown crystallite has a special orientation relative to the substrate, namely, the *b* axis stands on the substrate surface at an oblique angle of ~ 32°, and planar molecules are stacked in parallel along the *b* axis. To observe the molecular image, therefore, the crystallite was tilted by a special holder with an oblique spacer. The observation was carried out in a JEM 100C.

The critical dose of copper phthalocyanine was found to be $1–2$ C cm^{-2} by measuring the complete fading of a diffraction spot (Reimer[5]). High resolution, however, requires many separate diffraction spots to construct the image, and therefore, as stressed above, the electron beam must be reduced below the critical dose. Although the electron dose was not directly measured, it was estimated as ≤ 0.1 C cm^{-2} from exposure meter readings.

Figure 1*a* shows a high resolution micrograph, taken at ~ 70 nm under focus. It can be seen that the micrograph is extremely noisy, a result of using minimal beam irradiation and X-ray film with a large grain. We used an objective aperture of 20 μm in diameter—through which spatial frequencies of up to 1.55 nm^{-1} could pass. Computer simulation would give the shape of the molecule under optimal focus condition (60–80 nm underfocus) but its shape would be poor[6]. We retrieved the molecular shape by using a lot of periodic unit cells, as described by McLachlan[7], and Fig. 1*c* represents a retrieved image from the region well defined in Fig. 1*a*, from which an optical diffraction pattern represented the considerable conservation of structure details with a slightly asymmetric intensity distribution from the original electron diffraction pattern. We can see the shape of the molecule clearly in Fig. 1*c*. Figure 1*b* represents the relationship between the averaged image and an assumed structure based on the close isomorphic relationship to platinum phthalocyanine, with a slight rotation of ~ 18°.

These pictures strongly suggest that a reconsideration of the crystal structure is in order. We are trying to improve our experiment by combining high resolution micrograph with

intensity data from electron diffraction patterns, as described by Unwin *et al.*[8].

We thank Mrs H. Murata for purification of crude copper phthalocyanine. Y. M. also thanks the SRC for support.

Hot lines in the Earth's mantle

THE mantle 'hot spot' or 'plume' hypothesis of Wilson[1] and Morgan[2] has been used to explain linear chains of volcanic islands and seamounts as well as aseismic ridges. These features of the ocean basins were presumably caused by the motion of lithospheric plates over mantle plumes, since it is assumed that unusually intense volcanism occurs at the Earth's surface above mantle plumes. Initially it was suggested that hot spots do not move relative to the lithosphere or to each other[1,2], but it was later proposed that some hot spots undergo a limited amount of motion relative to each other[3,4]. Here we hypothesise that some linear volcanic chains are the expression not of lithospheric motion over mantle hot spots but of 'hot lines' in the mantle, above which volcanism occurs intermittently.

The idea of mantle 'hot lines' is based on data collected on Easter Island (south-eastern Pacific) and along the tectonic-volcanic lineation running eastwards and westwards from the island. Wilson[1] and Morgan[2] originally suggested that Easter Island marks the site of one of the major 'hot spots' in the Earth's mantle. The island consists of volcanic rocks, mainly basalt, but with significant quantities of more acidic types, including mugearite, trachyte and rhyolite (ref. 5 and E.B., C.G.A.H., D. E. Fisher, J. Honnorez, J. G. Schilling, J. J. Stipp and M. Zentilli, to be published). The petrology and geochemistry of these rocks (to be published) show close similarities to rocks of other areas interpreted as expressions of mantle plumes, such as Iceland[6,7]. The Easter Island basalts are richer in alkalis, iron and titanium, and large-ion lithophile elements (such as Ba, Sr

and Zr) than ocean basalts. They are enriched in light rare earth elements, and have $^{87}Sr/^{86}Sr$, ^{207}Pb and $^{204}Pb/^{206}Pb/^{204}Pb$ ratios in a range higher than ocean ridge basalts but similar to Iceland basalts (to be published). Volcanism which gave rise to the island occurred less than 2 Myr before present, and mainly within the last 1 Myr (to be published). Thus, the petrology and age of Easter Island are consistent with a mantle plume origin.

If the Easter plume was active in the past, a trail of volcanoes should exist east of the island, along the direction of motion of the Nazca plate, and their age should increase with distance from the island. Indeed, a chain of volcanic islands and sea-mounts is observed along the so-called Easter Island Fracture Zone (to be published), including the islands of San Ambrosio and San Felix, and extending probably close to the Chile Trench (Fig. 1). The petrology of the islands of Sala y Gomez, San Felix, and San Ambrosio, and of a number of seamounts along the Easter Line, is consistent with a mantle plume origin (to be published). The ages of volcanism along the Easter Line, coupled with the spreading history of the Nazca plate, indicate, however, that the Easter volcanic chain cannot be explained by a fixed, single mantle plume.

On the basis of identification of magnetic anomalies, Herron[8] demonstrated that the East Pacific Ridge in the south-eastern Pacific became an active spreading centre about 9 Myr BP; before this, the fossil Galapagos Rise (Fig. 1) was an active spreading centre. Anderson and Sclater[9] reached similar conclusions using the age–depth relationship of Sclater *et al.*[10], even though their model of the spreading history of the Nazca plate differs in some respects from Herron's[8]. Either model would require the development of a gap of several hundred kilometres in the volcanic chain along the Easter line, if a fixed mantle plume under Easter Island is the cause of the volcanic chain (to be published). Our surveys and the topographic map of Mammerickx *et al.*[11] indicate that no such gap exists; therefore the Easter volcanic line cannot be caused by a single fixed mantle plume beneath Easter Island. Either a plume existed at the intersection of the Galapagos Rise and the Easter Line when the former was active, and moved to the Easter Island area when the Galapagos Rise became inactive, or two plumes coexisted, one in the Easter Island area, one at the Galapagos Rise (to be published).

The age of volcanism along the Easter line confirms that the volcanic chain could not have originated solely from the motion of the Nazca plate over the Easter Island hot spot. Sala y Gomez was active 1.7 Myr ago, so it could not have formed at the site of Easter Island unless one assumes unreasonably high spreading rates. San Felix and San Ambrosio, located more than 2,700 km from Easter Island, were formed not earlier than one or a few million years ago, and still show signs of activity (to be published).

We conclude that the activity which gave rise to the Easter volcanic line took place intermittently at several sites along the line (Fig. 1). This observation, coupled with the fact that the products of this activity are of the type ascribed elsewhere to mantle plumes, leads us to propose that a thermally anomalous linear zone exists in the mantle beneath the Easter line. This mantle hot line is the cause of the intense volcanism along the Easter line.

We find it unlikely that the Easter line is simply a fracture zone caused by thermal contraction of the lithosphere[12,13] and that the igneous activity along it is solely the passive result of the lithospheric fracture–fracture zones such as those from the East Pacific (Mendocino, Murray, Clipperton and so on) and from the Atlantic (such as Romanche, St Paul and Vema), presumably caused in part by lithospheric contraction, are characterised by little or no volcanism. The intensity of volcanism along the Easter line, and the fact that the magma source is probably deeper than the source of ocean ridge magmas, suggest that the Easter hot line reflects processes initiated beneath the lithospheric plates.

Based on theory and laboratory experiments, two types of mantle convective flow have been postulated by Richter and
Fig. 1 Schematic illustration of the Easter hot line, showing the distribution of islands and of known seamounts in the area. Vertical full arrows indicate sites of young (< 2 Myr) volcanism; vertical open arrow indicates site of old (~10 Myr) volcanism at the intersection of the Easter line and the fossil ridge. The small Easter plate is described by Herron[16]. The Easter hot line is shown as due to Richter[14,15] mantle convective rolls; upwelling spouts[14,15] may actually be responsible for the line. △, Islands; ▲, seamounts.

Richter and Parson[14,15]. The first is a large scale flow, consisting of the plates themselves and of the return flow necessary to conserve mass, and the second a small scale flow, approaching a Rayleigh–Benard type convection, assumed to reach depths of about 650 km (where a major seismic discontinuity exists), with a similar horizontal scale[14,15]. The small scale convection rolls tend to become aligned with their axes parallel to the direction of motion of the plate—in times of 20–50 Myr for fast moving plates (10 cm yr^{-1}) but as much as several hundred million years for slow moving plates (2 cm yr^{-1}) (refs 14 and 15).

We suggest that the Easter hot line is the expression of mantle activity occurring along the rising limbs of adjacent Richter[14,15] convective rolls, with their axes parallel to the direction of motion of the Nazca plate. The required condition of relatively high plate velocity is probably fulfilled or at least approached in the Nazca plate, if we assume that the velocity of plates relative to the sublithospheric mantle is related to the measured spreading rates (~ 10 cm yr^{-1}) (refs 8 and 9). Making the same assumption, the direction of the Easter hot line is also the correct direction for a Richter convective roll, as it is almost exactly parallel to the direction of spreading. On the other hand, at lower plate velocities a pattern of mantle flow develops which is characterised by both upwelling and downwelling spouts, also aligned parallel to the direction of plate motion[12].

If the horizontal scale of each cell in the transverse convective rolls is about 650 km (refs 14 and 15), the distance between upwelling spouts would be roughly twice that distance. The San Felix–San Ambrosio 'hot' area is roughly 2,800 km from Easter Island or 2,600 km from a middle point between Easter Island and Sala y Gomez, and the fossil 'hot spot' at the Galapagos Rise was roughly halfway between the Easter–Sala y Gomez and the San Felix–San Ambrosio hot area. Thus, the distance between hot areas along the Easter line (roughly 1,300 km) is consistent with Richter and Parson's model.

We conclude that the Easter hot line is the result of mantle convection rolls or spouts aligned parallel to the direction of plate motion. The small Easter Plate[16] may be the result of complex interaction of two patterns of mantle flow at the intersection of the Easter line and the East Pacific Rise. It is possible that a hot line exists also west of the East Pacific Rise, extending into the Pacific Plate, along a chain of islands and seamounts up to Pitcairn Island. Pitcairn is < 1 Myr old[17].

Hot lines differ from 'normal' fracture zones in that the latter are primarily the result of lithospheric contraction[12,13], with the sublithospheric mantle having a passive role and consequently with little or no mantle-derived volcanism. The 'hot lines' are instead caused by activity of the sublithospheric mantle, as in Richter and Parson's model, and are characterised by volcanism of a type previously ascribed to mantle plumes. It is possible that some oceanic aseismic ridges are caused by mantle 'hot lines' rather than by motion of plates over hot spots.

Acoustic response to chemical stimuli in ground crickets

IN several species of ground crickets (Orthoptera, Gryllidae, Nemobiinae), chemical communication may be used in addition to acoustic communication in bringing males and females together. In laboratory experiments, a high proportion of males of three *Allonemobius* species and one *Pictonemobius* species showed rapid antennation and produced calling songs shortly after exposure to paper from the cages of female crickets. This is the first report of an acoustic response to chemical stimuli in singing Orthoptera.

Populations of *A. fasciatus*, *A. allardi*, *A. tinnulus* and *Eunemobius carolinus* were studied where they occur in sympatry in Suffolk County, Long Island, New York, in 1972, 1973 and 1974. *A. fasciatus* and *A. allardi* were also studied in Tompkins County, New York in 1974. In addition, sympatric populations of *A. fasciatus* and *P. ambitiosus* were studied in Gainesville, Florida, in 1975. Several *A. sparsalsus* males were collected in Florida (by T. J. Walker) and then studied in New York in 1974. The male crickets used in experiments were field captured, except for 33.3% of the *A. tinnulus* males and 18.9% of the *A. fasciatus* males, which were laboratory reared.

Adult males were kept individually in small cages for 1 week before testing. The cage of each male was carried from a rearing area to an experimental area where the cricket was placed in a plastic box (35.5 × 28 × 15 cm) containing one of the following stimuli: (1) control, clean paper towels; (2) paper conditioned in the rearing cages of female crickets (usually 12 virgin females); (3) paper conditioned by males (groups of 8–12 adult male crickets); (4) live females (usually 12 virgin females). All experiments were carried out under laboratory light during the 'on' periods of the rearing room light cycle, at temperatures between 22 and 28 °C. In experiments with paper, a stopwatch

Fig. 1 Proportions of *A. fasciatus* (*a*), *A. allardi* (*b*) and *A. tinnulus* males (*c*) that sang in tests with control paper (C), female-conditioned paper (♀P) and live females (♀♀). For each species, a significantly greater proportion sang on female-conditioned paper than on control paper. A significantly greater proportion of *A. allardi* males sang in the presence of live females than on female-conditioned paper. Numbers above bars refer to number of males tested.

was started when the male was dropped into the box; in experiments with live females, timing was begun when the male made antennal contact with a female. The watch was stopped at 5 min, or when the male began to stridulate. A stridulatory response within 5 min was noted as a positive response. Each male was tested only once with a given stimulus; for stimuli other than controls, males were tested only once every 24 h.

In addition to the main series of experiments, *A. fasciatus* males were tested with paper from the cages of early instar and older male *A. fasciatus* juveniles (that is, juveniles without visible ovipositors).

Many of the males gave a vigorous positive response in tests with paper conditioned by females (Figs 1 and 2). These males walked in the test box for several seconds after being placed on the paper, slowly antennating and palpating the substrate. Often, the cricket showed an obvious increase in the rate of antennation and made frequent erratic changes in body orientation, as though searching. Soon, usually within seconds, the male raised his tegmina (forewings) and stridulated. Some males stood still and sang, others slowly walked while singing.

A wide range of behaviour was shown by males that did not respond with song to conditioned paper. Some were completely inactive in the test box, others made the transition from ex-

Fig. 2 Proportions of *P. ambitiosus* (*a*), *E. carolinus* (*b*) and *A. sparsalsus* males (*c*) that sang in tests with control paper (C), female-conditioned paper (♀P) and live females (♀♀). A significantly greater proportion of *P. ambitiosus* males sang on female-conditioned paper than on control paper. Numbers above bars refer to number of males tested.
ploratory walking to the quick searching behaviour, but produced no song within 5 min.

The numbers above the bars in Figs 1, 2 and 3 are the numbers of males tested with each stimulus; the height of the bars shows the proportion of males that sang within 5 min. For *A. fasciatus*, *A. allardi*, *A. tinnulus* and *P. ambitiosus*, the proportion of males that sang in response to paper conditioned by conspecific females was significantly greater than the proportion that sang on the control paper ($P < 0.05$ in 2×2 *G* tests of independence[1]; Figs 1 and 2). In the absence of visual, acoustic, or tactile cues, males of the four species sang in response to some factor, presumably chemical stimuli left on the substrate by females. None of the *Eunemobius carolinus* and *A. sparsalsus* males gave a positive response in the presence of conspecific female paper.

A. fasciatus, *A. allardi*, and *A. tinnulus* males showed a significantly greater response to conspecific female paper than to paper conditioned by conspecific males (Fig. 3). Furthermore, *A. fasciatus* males showed a greater response to paper conditioned by adult females than to paper conditioned by *A. fasciatus* juveniles (Fig. 3). These results suggest a sexual role for chemical communication in these species. Ground crickets of these genera produce quiet, high pitched songs relative to those of field crickets (subfamily Gryllinae), or even other nemobiine genera (for example, *Eunemobius*)[2]. The softer, higher pitched songs are not likely to carry far to attract females at a distance. Perhaps the song-releasing stimuli left on the substrate by females are pheromones which indicate areas where singing males are most likely to attract females. The stimuli may be important in species isolation; I have experimental evidence of specificity at the species level[2].

Fig. 3 Proportions of *A. fasciatus* (*a*), *A. allardi* (*b*) and *A. tinnulus* males (*c*) that sang in tests with female-conditioned paper (♀P) male-conditioned paper (♂P); and juvenile-conditioned paper (JP) for *A. fasciatus*. For each species a significantly greater proportion sang on female-conditioned paper than on male-conditioned paper. A greater proportion of *A. fasciatus* males sang on female-conditioned paper than on juvenile-conditioned paper. Numbers above bars refer to number of males tested.
Previous studies have described pheromone-like communication in crickets[3,4] and chemically-induced stridulation has been reported for the Douglas fir beetle[5]. The data reported here, however, demonstrate song-releasing chemical stimuli in insects well known for their acoustic communication. Further studies may reveal something about the evolutionary origins of cricket song. In some cockroach species (for example, *Blattella germanica*) males raise their wings and expose gustatorial glands (which females feed on) in response to antennal contact with a female pheromone[6,7]. This is of interest here since crickets are believed to have a cockroach-like ancestor[8].

At present, the origin and nature of the song-releasing stimuli are unknown. Initial attempts to isolate stimuli from the faecal pellets of females have resulted in ambiguous bioassays.

I thank Drs T. J. Walker and R. Hoy for comments; the

Changeable coloration of cornea in the fish *Hexagrammos octogrammus*

ALTHOUGH fish are considered 'lower' vertebrates, the visual apparatus of some species has a high degree of adaptability unparallelled in other vertebrates. For example, members of the Hexagrammidae can change their cornea rapidly from colourless in the dark, to deep red in bright light[1,2]. We have studied this ability in *Hexagrammos octogrammus* Pallas, a common shallow-water fish of the Japan Sea, and found that it is caused by the effects of illumination on the distribution of coloured cytoplasm in the corneal chromatophores.

Specimens of *H. octogrammus* caught by night or kept in the dark have a cornea as transparent and colourless as that of most fish. But specimens collected in their natural environment by day, or kept in an illuminated aquarium, have a bright orange or deep red cornea. If a light-adapted fish is placed in the dark, its cornea gradually pales, becom-

Fig. 1 Absorption spectra measured in pupil zone of corneas from *H. octogrammus* in different adaptation states: *a*, in full darkness; *c*, intermediate (yellow) coloration observed after about 30 min in sunlight after full dark adaptation; *d*, full coloration after 2 h in sunlight; *b*, yellow cornea of *Pleurogrammus monopterigius* in full colour; *e*, control.
Fig. 2 Reconstruction of anterior part of the eye in *H. octogrammus*. SC, Chromatophores; C, chondreal sclera; I, iris.

ing yellow and then colourless. Similarly, in bright illumination, a colourless cornea becomes yellow and then red, even at night. The speed of colour change depends on the intensity of illumination, and when a fish is transferred from direct sunlight to darkness, complete decoloration usually takes 1.5–2 h. If the fish is kept continuously in light intensities of about 10 lx, its cornea becomes yellow without reddening.

The cornea of *H. octogrammus* has surprising absorptive properties as a colour filter. Its transmittance in the pupil zone in the light-adapted state does not exceed 0.3% for wavelengths of 400–500 nm. It absorbs more than 10% of the light up to a wavelength of 580 nm (Fig. 1). The most saturated coloration reported so far for a fish cornea has been that of the South American *Astronotus* (Cichlidae)[3]— yet in this species the minimum transmittance is not less than 4%, absorption above 10% being observed only for wavelengths shorter than 510 nm.

This changing corneal coloration can be compared with retinomotor and pupil reactions, which regulate the quantity of light reaching the receptor layer. The most likely function of the yellow and orange coloration is to improve the resolution of the eye by eliminating harmful loss of contrast of retinal image due to (1) a blue veil of light scattered on intraocular and extraocular media, and (2) chromatic aberration[4], which can be quite significant in the fish eye[5]. Thus shallow-water fishes like *H. octogrammus* searching for food on a well-lit substratum can benefit from a coloured cornea in spite of the loss of sensitivity because it is only at low light intensities that preretinal filters become a disadvantage. The exceptional saturation of the filters in *H. octogrammus* is tolerated because the fish can, so to speak, remove its sunglasses when it gets dark.

In most animals there is diffuse coloration of some part of the eye—in tree shrew, ground squirrels and diurnal snake the whole lens is yellow[4], in others, as in some squid[6]. a distinct layer of lens or of the cornea, as in the perch and pike, is coloured. In *H. octogrammus* the cornea is coloured

by specialised corneal chromatophores, which differ considerably in structure from ordinary dermal chromatophores.

Chromatophore cell bodies comprise two compact sickle-shaped masses near the upper and lower edges of the cornea, outside the pupil zone. In a vertical section of the cornea, cell masses are surrounded by fibrous tissue. Each chromatophore (50–70 μm in diameter) is pear shaped and gradually tapers into a single, flattened process. All processes are oriented vertically (in the eye of a living fish) and extend downwards or upwards, according to the position of the cells in the upper or lower cell mass, and overlap the pupil zone (Fig. 2).

Corneal coloration is altered by redistribution of coloured cytoplasm between cell bodies (Fig. 3) and their processes. Direct observation of the living fish under a dissecting microscope showed that in fish kept in bright light the processes are filled with cytoplasm, but in the dark they become empty and invisible.

There are two kinds of corneal chromatophore—deep red and yellow—resembling dermal erythrophores and xanthophores in their coloration. When a dark-adapted fish is exposed to bright light, the processes of the yellow chromatophores fill up first, giving a transient yellow colour to the cornea (Fig. 1c). The corneas of *Pleurogrammus monopterigius* and *H. stelleri* (both Hexagrammidae) have only yellow chromatophores, the colour of their corneas in the light-adapted state being similar to the intermediate coloration of that of *H. octogrammus* and the permanent colour of the cornea of pike and perch[7]. The absorption bands at 427, 455 and 485 nm reveal the carotenoid nature of the yellow pigmentation. The coloration of red cornea of *H. octogrammus* in light-adapted fish corresponds to absorption in the red corneal chromatophores, their absorption spectrum consisting of a single broad band (the half-band about 400–550 nm) with a single flattened maximum at

Fig. 3 Ultrastructure of the chromatophore from *H. octogrammus* cornea. Numerous lipid granules (LG), arborised invaginations of cell membrane (I), collagen fibres (C), pinocytosis vesicles (PV), mitochondria (M) and Golgi apparatus (GA) are visible. (× 29,750).
about 480 nm. The difference between the absorption spectra of the two types of corneal chromatophore, shown by microspectrophotometry, cannot be explained as resulting from differences in concentration of the same coloured substance.

The corneal chromatophores differ from other (dermal) chromatophores in having only one process, and having, in the cytoplasm of the cell body and process, homogeneous round granules of intermediate electron density (100–120 nm in diameter), which might be lipid droplets in which carotenoids are dissolved (Fig. 3). Both cell bodies and processes contain many microtubules (25 nm in diameter), lining the axis. No lipid granules have been found in the processes of dark-adapted fish, although microtubules and numerous pinocytosis vesicles are sometimes present. There are many invaginations of the cell membrane, up to 100 nm wide and several μm long, with pinocytosis vesicles attached to them. Unlike ordinary dermal chromatophores—erythrophores and xanthophores—the corneal chromatophores contain no pterinosomes[8].

Microtubules are directly concerned with dispersion and aggregation of pigment granules in melanophores[9,10], and antimitotic agents (colchicine and vinblastine) which destroy the normal function of microtubules may block the movement of pigment granules[11]. After injection of colchicine into the ocular bulb of *H. octogrammus* the response of cornea to a change of illumination is slower and weaker.

Changes of the corneal coloration caused by specific corneal chromatophores are not restricted to members of the Hexagrammidae. They have been observed, but to a lesser degree in several species of other families, such as the Blennidae, Cottidae and Tetraodontidae.

Aversive behaviour of crown-of-thorns starfish to coral evoked by food-related chemicals

WHEN *Acanthaster planci*, the coral-predating crown-of-thorns starfish, encounters living coral or when it is presented with coral extracts, it rears the arms near to the stimulus source aborally and retracts the tube feet of these arms into the ambulacral groove[1,2]. This aversive behaviour has generally been attributed to the effect of discharge of coral nematocysts[1-3], or to toxins released from nematocysts[4]. But arm rearing may be evoked before contact is made with corals, and both "withdrawal" responses are produced by non-coral food or food extracts which stimulate *A. planci* to feed (R.J.M., unpublished). This suggests that it is not nematocysts or their toxins which are responsible, but rather chemicals from coral tissue.

The experiments described here show that this is the case: the function of the aversive response seems to be protection of the starfish against nematocyst discharge on contact with coral.

The role of nematocyst toxins was investigated by comparison of the effects on *A. planci* of extracts of whole coral tissue and homogenised isolated nematocysts from three coral species, including *Millepora dichotoma* ('fire coral'), which is only rarely attacked by *A. planci*. To validate comparisons between the extracts of each species of coral, and show up any differences in activity, it was necessary to equalise concentrations of non-stimulatory components of the extracts. Collins[5] found that only low molecular-weight components of coral extract, apparently amino acids, elicited arm withdrawal. It was assumed that soluble protein represented the bulk of non-stimulatory material in both nematocysts and tissue cells, and so the protein concentrations of the extracts were equalised—by dilution of the more concentrated extracts—after estimation by the method of Lowry *et al.*[6].

Table 1 summarises the effects of dripping extracts near the tips of arms of moving starfish. It shows that the homogenised nematocyst preparation of only one coral, *Millepora dichotoma*, evoked stronger responses than those produced by the corresponding whole coral extract, and even then the responses evoked were weaker than those produced by the whole tissue extract of *Acropora multicaulis*, in spite of the far greater protein concentration of the *Millepora* extract.

Moreover, the high efficiency of isolation of nematocysts of *Millepora dichotoma* (Fig. 1) made possible an estimate of the proportion of total tissue volume in intact *Millepora* occupied by nematocysts: it was approximately 2%. Thus the contribution made by nematocyst contents to the arm-rearing and tube-foot retraction activity of a whole coral extract seems to be negligible.

We even found that intact isolated nematocysts had no observable effect on the tube feet of *A. planci*—yet accidental splashes of nematocyst suspensions on to our skin produced typical stinging sensations.

These unexpected results suggested that nematocyst contents had leaked into the whole coral extracts during preparation, although most nematocysts remain undischarged. This objection was negated by testing extracts of mesenterial filaments, which contain greater concentrations of nematocysts than other coral tissues (Fig. 2) and may be removed intact from corals with large polyps. Even so, as Table 1 shows, the responses elicited by the mesenterial

Fig. Photomicrograph of nematocysts isolated from 'fire coral, *Millepora dichotoma*, and used in the preparation of nematocyst extracts. The darker objects are fragments of coral skeleton. For further explanation, see text.

30μm

Table 1 Comparison of the effects on *A. planci* of extracts of whole coral tissue, homogenised nematocysts and mesenterial filaments

Coral	% Purity (approximate) of nematocyst preparation	Extract	Protein concentration (μg ml^{-1})	Mean response, % (to 5 drops and 10 drops, respectively)			
				Arm rearing		Tube-foot retraction	
Acropora multicaulis	60	Whole coral extract	100	8,	42	8,	33
		Homogenised nematocyst supernatant		0,	0	0,	8
Porites solida	50	Whole coral extract	73	0,	17	8,	17
		Homogenised nematocyst supernatant		0,	0	8,	8
Millepora dichotoma	85	Whole coral extract	680	0,	25	8,	25
		Homogenised nematocyst supernatant		8,	33	8,	33
Fungia fungites	—	Whole coral extract	62	25,	58	33,	67
		Mesenterial filament leachings		8,	42	8,	42
		Homogenised filament supernatant		17,	42	17,	42
Platygyra lamellina	—	Whole coral extract	85	33,	67	25,	33
		Mesenterial filament leachings		17,	42	8,	42
		Homogenised filament supernatant		8,	25	0,	42

Extracts of whole coral tissue were prepared by immersion of living corals in distilled water at 5 °C for 12 h, followed by centrifugation to remove cell debris, zooxanthellae and nematocysts, rotary evaporation to dryness, and redissolution in seawater. To isolate nematocysts, uncentrifuged whole coral extracts were fractionated by differential sedimentation to separate nematocysts from cell debris and zooxanthellae. The nematocyst preparations were homogenised in seawater to discharge them and break up the capsule, and then centrifuged. Corals were induced to extrude their mesenterial filaments by scrubbing, and the filaments were collected using forceps. They were then left overnight in filtered seawater at 5 °C, shaken to break up the structure, and centrifuged: the supernatant was tested as "leachings". The third extract was produced by homogenising the centrifugate—consisting of remaining tissue and nematocysts—followed by centrifugation. The supernatant was tested as "homogenised filament supernatant". The extracts were tested on four starfish by dripping at a rate of about one drop per s on to spots 1 cm from three arm-tips of moving starfish, avoiding dripping directly on to tube feet. The mean responses are to 5 drops and 10 drops, delivered concurrently, and were calculated by grading the strengths of responses on a four-point scale (0 to $+++$), averaging, and rounding off to the nearest whole number. As far as possible, the same animals were used for testing different extracts of the same coral species.

filament extracts are, in nearly all cases, weaker than those produced by whole coral extracts.

It thus seemed clear that neither nematocysts nor their contents were primarily responsible for the arm and tube-foot "withdrawal" responses evoked by coral extracts, although the nematocysts in living coral may have some effect. This suggested that the aversive responses constitute at least partly a response to food-related chemicals, and we conducted a search for arm-rearing activity in low-molecular-weight compounds known to be responsible for feeding attraction in other marine invertebrates[7,9]. The results are summarised in Table 2.

When the chemicals were tested individually, only betaine produced arm-rearing activity at concentrations low enough to suggest its presence in coral as an active ingredient. But a synergistic effect seems to operate when mixtures of the chemicals are tested, as observed in some other marine invertebrates[7-9].

The link between arm rearing and feeding in *A. planci* was confirmed by the finding that a mixture of betaine and three amino acids potent at inducing arm rearing— arginine, proline and glutamic acid—induced stomach

Fig. 2 Photomicrograph of a fragment of a mesenterial filament from the brain coral *Platygyra lamellina*, showing the high concentrations of nematocysts present. Two types may be distinguished where the nematocysts have been ejected from the surface of the filament by the pressure of the slide coverslip.

50μm
eversion in five out of nine starfish tested, using Collin's[5] assay for feeding-inducing activity.

To examine for the presence of betaine and the amino acids in coral tissue, the ninhydrin-positive fraction of the low molecular-weight fraction of an extract[4] of *Acropora* sp. was run in several sample strips alongside betaine standards and standard mixtures of the amino acids, on a paper chromatogram in a descending medium of butanol-acetic acid–water (3 : 1 : 1). When developed with a stain for alkaloids[10] it revealed a spot on the coral fraction strip running in the same position as betaine. The eluate of part of another sample strip corresponding to the alkaloid spot induced arm rearing in only two out of six trials, but the eluate of the rest of the strip possessed no activity. It thus seems likely that betaine, or another alkaloid with similar R_f in the solvent used, is the most potent factor in eliciting the arm-rearing response.

On another sample strip on the chromatogram, staining with ninhydrin revealed spots which corresponded with the position of the amino acid standards: thus their presence in coral tissue is also very likely.

Thus we found that arm rearing in *A. planci* can be induced by chemicals present in coral tissues which also stimulate it to feed. A consideration of the morphology of asteroids leads us to expect some raising of arm-tips in response to chemicals derived from prey, to aid the tube feet in location of epifaunal prey, and this is borne out by the literature[11–14]. In *A. planci*, however, the full response seems to be exaggerated beyond that of other asteroids, the arms being raised and curled back along their entire length.

Although our results suggest that nematocysts are directly responsible only to a limited extent for the aversive reaction of *A. planci* when it encounters living coral, it is certainly under threat from them, as discharged nematocysts have been found attached to tube feet after contact with coral tentacles (R.J.M., unpublished). It seems likely that the exaggerated arm curling, triggered by chemicals derived from coral tissue, serves to protect the tube feet against excessive nematocyst discharge on contact with coral. While this protection cannot be complete, the strength of the nematocyst defences of a coral species may not be as important as has been suggested (refs 1 and 2 and unpublished results of R. F. G. Ormond, H. J. Hanscomb and D. H. Beach) in determining the acceptability of that species to *A. planci* as prey.

We thank Dr S. M. Head for identification of corals, and Drs. A. C. Campbell, A. R. S. Collins and R. F. G. Ormond for helpful discussions. The work was financed by the British Ministry of Overseas Development.

Hybrid crown-of-thorns starfish (*Acanthaster planci* x *A. brevispinus*) reared to maturity in the laboratory

THE coral predators *Acanthaster planci* L. and *A. ellisii* (Gray) have been the subject of many publications in recent years. But there is another little known *Acanthaster* species, *A. brevispinus* Fisher, which was described from two specimens dredged in the Sulu Archipelago, Philippine Islands[1]. The species has been reported from the Great Barrier Reef region, Queensland[2,3] and specimens have been collected recently off Townsville, North Queensland, from sandy substrates and not on coral reef. Although *A. brevispinus* differs conspicuously from the other species in having very short and numerous spines on the aboral disk surface, Madsen[4] and Caso[5] were dubious of its status in their reviews of the genus *Acanthaster* Gervais. Phenotypic variation of *A. planci* was suggested in verbal discussion among Australian biologists. We describe here a resolution of the status of *A. brevispinus* by *in vitro* crosses with *A. planci* which led to the rearing of hybrid starfish.

Ripe specimens of *A. brevispinus* were collected by trawling in December 1973, near the time of annual gamete release by *A. planci* in Great Barrier Reef waters[6]. Gonads were dissected from starfish of both taxa. Ovaries were treated with 10^{-5} M 1-methyladenine in seawater to mature the oocytes[7], which were fertilised *in vitro* at 28 °C with sperm suspensions. Four groups of larvae, that is, each species and reciprocal crosses, were reared from eggs using the technique which gave a high success rate for *A. planci* larvae[8]. The different larvae passed through similar bipinnaria and brachiolaria stages. Numbers of late stage larvae in each batch represented 10–20% of the original numbers of eggs, except for the *A. brevispinus* batch in which only a few normal late brachiolariae developed. After 4 weeks, late larvae were transferred to static conditions with settlement substrates of coralline algae, coral skeleton and filamentous algae.

The newly metamorphosed starfish were five-armed and

Solutions were tested by dripping 10 drops at about one per s about 1 cm from an arm tip of a moving starfish. Ten or 20 trials were performed for each solution and individual starfish were generally tested twice. The results are expressed as the percentage of trials in which rearing was observed.
Fig. 1 Aboral views of starfish. *a*, *A. planci* (215 mm diameter); *b*, *A. brevispinus* (225 mm); *c*, *A. planci* hybrid (210 mm); *d*, *A. brevispinus* hybrid (210 mm).

0.4–1.0 mm in diameter. They fed on encrusting algae. Many failed to develop normally and, 6 weeks after metamorphosis, 60 *A. planci*, 30 *A. planci* hybrids, six *A. brevispinus* hybrids and no *A. brevispinus* remained. (For brevity, hybrids are named after the maternal taxon.) At this time, the young starfish were transferred to aquaria in a recirculating seawater system 33–35‰ salinity and 25±3 °C, and provided with coralline algae on coral skeletons for food. The three kinds of young starfish grew and added arms in the order described for *A. planci* by Yamaguchi[9]. Five to seven months after metamorphosis they achieved their adult number of arms and about this time commenced feeding on coral polyps, *Pocillopora damicornis* and *Acropora acuminata*, provided in addition to coralline algae. Late in their second year of development, the hybrid starfish and *A. planci* developed gonads with normal gametogenesis (sampled by biopsy). Sizes at 1 and 2 yr of age are shown in Table 1.

It is impossible to distinguish hybrid starfish and *A. planci* by morphology during the early months of development. But hybrids with a diameter of more than 200 mm have conspicuously shorter spines than *A. planci* and longer spines than *A. brevispinus* (Figs 1 and 2). In other features in which *A. planci* and *A. brevispinus* differ consistently,

the hybrid starfish show intermediate conditions, that is, density of aboral disk spines, length of aboral pedicellariae, length and number of adambulacral spines, shape of subambulacral spines, interradial marks on the disk and taper of arms. The intermediate hybrid features may be more similar to one parental condition, that is, on the aboral disk surface of hybrids, spine length approximates more to the *A. brevispinus* condition (Fig. 2), while the pedicellariae are slender, resembling those of *A. planci*. There are no consistent differences between *A. planci* hybrids and *A. brevispinus* hybrids. Some *A. planci* show a persistent "bull's-eye" pattern on the aboral surface from a pale ring of papulae (dermal evaginations) (Fig. 1*a*). One of three *A. brevispinus* hybrids shows the pattern (Fig. 1*d*); none of twelve *A. planci* hybrids shows the pattern.

A. planci and *A. brevispinus* differ in habitat and morphology and also in their feeding behaviour. Scallops, *Amusium balloti* and *Amusium pleuronectes*, occur in the habitat of *A. brevispinus*, and in the laboratory *A. brevispinus* traps and eats live scallops beneath the disk. It shows an arched posture when digesting live and dead scallops and scallop flesh. *A. planci* never traps live scallops and never arches when feeding on scallop flesh. (*A. planci*

Table 1 Diameters of starfish, *A. planci* and hybrids, reared in the laboratory

| | 1-yr-old | | 2-yr-old | |
	Mean diam. (mm)	Range (mm)	Mean diam. (mm)	Range (mm)
A. planci	33.4	18.0–61.2 (17)	198	145–255 (13)
A. planci hybrid	30.8	19.7–44.1 (8)	199	165–250 (9)
A. brevispinus hybrid	36.4	35.7–37.0 (2)	223	215–230 (3)

Numbers of individuals measured are given in parentheses.

Table 2 Reactions of starfish, *Acanthaster* species and hybrids, to live scallops

	Nos of Individuals	Recorded hours of activity	Mean contacts with scallop per h of activity
A. planci	3	43.6	0.50
A. planci hybrid	5	107.0	1.94*
A. brevispinus hybrid	3	62.9	2.31*
A. brevispinus	3	19.9	3.52

The three *A. brevispinus*, 220–240 mm diameter, were tested 3d after collection. The others were laboratory-reared starfish, 160–190 mm diameter, which had been fed solely with algae and coral before this experiment. Each starfish was placed in a glass aquarium 30 × 30 × 50 cm with running seawater and continuous illumination. Activity was recorded by an 8-mm movie camera, situated above the aquarium, making exposures at 30-s intervals. The starfish was accustomed to the apparatus for a day and then a live scallop, *Amusium pleuronectes*, was added and filming commenced. Duration of filming was 27–31 h. Film strips were analysed frame by frame. Each new contact with the scallop by the starfish, that is, passing at least part of an arm over the scallop, and periods of quiescence were recorded. Data for each starfish were recorded as numbers of contacts per unit period (h) of locomotion in case contacts with scallops were purely incidental, being related only to the amount of activity. Numbers of 0, 1 . . . 6+ contacts per hour were accumulated for each kind of starfish. For statistical analyses, these numbers were adjusted to 100 h total activity and the numbers in each category for two kinds of starfish compared by χ^2 analysis.
*These data are not significantly different ($P < 0.5$); they are the only data for two kinds of starfish which are not significantly different ($P < 0.001$) (see explanation of statistical analysis above).

normally feeds on hermatypic coral, but it will accept a range of animal flesh when hungry.) The hybrid starfish trap scallops and they may adopt an arched posture, although not as pronounced as *A. brevispinus,* when feeding on scallops. Further evidence of behavioural reactions to scallops by hybrid starfish, inherited from their *A. brevispinus* parent, is shown in Table 2. Hybrid starfish reared on coral showed a significantly greater rate of contacts with scallops than *A. planci* of similar experience. Contacts with the scallop usually occurred when the starfish moved towards it across the floor of the aquarium and contact was often terminated by the scallop escaping with rapid valve movements.

It has been shown that the starfish described as *A. brevispinus* are genetically different from typical *A. planci* : crossing them produces starfish which differ in morphology and behaviour from *A. planci* reared in the same conditions. There is no evidence of gamete incompatibility between the two taxa, as found in interspecific crosses attempted with other asteroids[10,11]. There is obviously a high degree of genetic compatibility between them, at least to F_1 hybrids. But they are isolated in the field by their habitat preferences, *A. planci* on coral reefs and *A. brevispinus* in deeper water on sandy substrates. Although probably they both spawn during summer in Great Barrier Reef waters, the chance of cross fertilisation is remote: ripe *A. planci* spawn in response to a pheromone released with gametes by neighbouring individuals[12] and this mechanism is unlikely to operate over hundreds or thousands of metres, with consequent dilution of the pheromone and gametes. No natural intermediate forms have been found in the Great Barrier Reef region,

Fig. 2 Maximum disk (*a*) and arm (*b*) spine lengths on the aboral surfaces of *Acanthaster planci* (●), *A. brevispinus* (▲), *A. planci* hybrids (○) and *A. brevispinus* hybrids (△). Regression lines were fitted by least squares method (hybrid data pooled).

although the reef environment has been surveyed extensively by biologists aware of the morphology of *A. brevispinus*[13,14].
A. planci and *A. brevispinus* are taxa which do not interbreed in a region of sympatry. They are species retaining a high degree of genetic compatibility, suggesting recent speciation. It is notable that the morphological differences between *A. planci* and *A. brevispinus* are much greater than the morphological variation of *A. planci* throughout its wide Indo-Pacific distribution and between *A. planci* and the eastern Pacific taxon, *A. ellisii,* which is of disputed status[15,16]. If degree of morphological difference within this genus even approximately reflects degree of genetic difference, then all populations of *A. planci* and *A. ellisii* are genetically compatible. These suggestions are in accordance with a recent evolution of *A. planci* and dispersal through the Indo-Pacific region. It seems more likely that *A. planci* evolved from an ancestor like *A. brevispinus* than vice versa. *A. planci* is atypical of coral reef asteroids in its large size and often conspicuous mode of life. It is more probable that an atypical, specialised, coral predator evolved from an unspecialised, sand inhabitant than vice versa. In this case, development of large sharp spines from the small blunt spines of *A. brevispinus* gave the means of protection from the numerous predators which are a particular hazard of the habitat and mode of life adopted by *A. planci.*

This is the first time that asteroid hybrids have been reared successfully in the laboratory. The only other reported cross fertilisations resulted in abnormal embryos or malformed early larvae[10]. In contrast, there is an extensive literature on echinoid hybridisation with crosses involving quite divergent taxa[17]. Although almost no echinoid hybrids have been reared beyond plutei, hybrids from reciprocal crosses between the sand dollars *Dendraster excentricus* and *Encope californicus* have been reared to young urchins and in these hybrids paternal characters predominate[17]. In *A. planci* and *A. brevispinus* hybrids, characters of neither parent predominate and the hybrids generally show intermediate conditions.

Cultivation of larvae of Japanese eel

ALTHOUGH the breeding place of the European eel has been detected[1], the morphology and ecology of their larvae, especially in pre-leptocephalus stages, still remain to be investigated. We have, however, succeeded[2-4] in obtaining some pre-larvae of the Japanese eel, *Anguilla japonica*, following artificial induction of maturation and spawning in aquaria. The larvae survived for only 6 d; their teeth characteristic of muraenoid larvae were merely in the state of anlagen and their eyes were completely devoid of retinal pigment. Further information of the early development of the eel is therefore required to enable elucidation of their life history. Here, we describe the larvae of Japanese eel developing for up to 14 d in the laboratory.

Silver eels were collected in the Hiranuma and Mabuchi Rivers in Aomori prefecture (Japan) in September 1975. Females and males were matured with repeated injections of chum salmon pituitary homogenate and Synahorin (Teikoku Zoki), respectively[5,6]. Eggs were stripped from the females, placed into glass dishes and inseminated by the dry method with the sperm of 2 or 3 males. The eggs were kept in seawater at 23 °C until they hatched. The larvae were reared at 23 °C on the day of hatching. Subsequently the larvae were maintained at 19 °C.

The larvae survived for 14 d. The following description is based on the observation of the larvae from days 7 to 14 after hatching. Since larvae of that period of development are very weak and their tail is liable to shrink a little during microscopic observations, the measured values of body length and the myomere number of larvae

Fig. 1*a*, Head of larva, day 9 after hatching, × 25; *b*, head of larva, day 12 after hatching, × 22; *c*, larva, day 14 after hatching, × 13.5; *d*, head of larva, day 14 after hatching, × 38.5.

may be approximate. On day 7, the mean body length was ~6.2 mm, and on day 14, ~7.0 mm. The number of myomeres was 53–54 + 50 (pre- + postanal myomeres) 7–10 days after hatching and 54 + 55–60 in those 11–14 days after hatching.

The larvae on day 7 had well developed tooth anlagen on the jaws and a large ventriculus cerebri in the brain. A broad embryonic fin enveloped the compressed body continuously from the posterior region of the head to the caudal margin of the vent. There was no trace of pigmentation except in the caudalmost part of the membraneous fin. By day 8, some black retinal pigment began to appear in both eyes (Fig. 1*a*) and after a further 12 h pigmentation of the eyes was fully developed. During that time the ventriculus cerebri became smaller. These larvae, unlike the earlier stages[4], were seen to swim in a horizontal position and to rest suspended in the water in a head-down attitude. From days 9 to 11 after hatching, both the upper and lower jaws developed considerably, and the tooth anlagen came to differentiate into definite teeth, which lengthened gradually, one after another. By day 12, sharp teeth were observed to protrude obliquely from the jaws (Fig. 1*b*). An oil drop near the cranial end of the yolk sac became extremely small. On day 14 after hatching, black pigmentation was still seen in the larvae, but only in the eyes and on the caudalmost tip of the membraneous fin (Fig. 1*c*). A pair of pectoral fins were present. The mouth which was directed downwards during the foregoing stages took a forward direction. The upper jaw had three pairs of shorter teeth in addition to the longest, grasping tooth, while the lower jaw had four pairs of teeth (Fig. 1*d*). The lower jaw moved occasionally, but the mouth did not close perfectly.

The most advanced larvae obtained seem to resemble closely the smallest European eel larvae collected by Schmidt[7] in the Atlantic Ocean. From these findings on both the European and the Japanese eel, a clearer outline of the morphological changes of the eel during the initial stage of its life cycle has been obtained.

Genetics of expression of xenotropic virus and autoimmunity in NZB mice

CERTAIN retroviruses (RNA tumour viruses) have been implicated in the autoimmune disease of New Zealand mice[1]. These mice produce large numbers of xenotropic retroviruses[2,3] and contain high concentrations of the retroviral envelope antigen gp 69/71 in their serum and tissues[4]. Moreover, gp 69/71 and the corresponding antibodies contribute to the immune deposits in the nephritic kidneys of NZB and (NZB × NZW)F₁ mice[4]. Nevertheless, it is not established that xenotropic viruses are the primary cause of the autoimmune disease of NZB mice. Conceivably, these agents may be involved only secondarily. The presence of RNA viruses in NZB mice may explain neither the production of antibodies against DNA, nucleoproteins, and erythrocyte antigens nor the anomalies of T- and B-lymphocyte function[5]. Transmission of autoimmunity has not been achieved
Fig. 1 Xenotropic virus titres in NZB and SWR mice and their crosses. All parental strains of mice were obtained from Jackson Laboratory, Bar Harbor, Maine. Spleen cell suspensions were prepared from the test animals as described previously[10] and assayed on the 81 cell line[11] for xenotropic virus as follows. The 81 cells were grown and the assay was carried out in McCoy's 5A medium (Grand Island), supplemented with antibiotics and 15% foetal calf serum. The 81 cells (2×10⁶) were seeded into 6-cm plastic Petri dishes. The next day the medium was withdrawn and the cells were treated with 2 ml DEAE dextran in McCoy's 5A medium without serum (25 μg ml⁻¹) for 30 min at 37 °C. Serial dilutions of spleen cell suspensions of 5 ml McCoy's 5A medium were inoculated on the 81 cells after the DEAE dextran was rinsed away. On days 3 and 10 after inoculation 3 ml medium was added (similar results were obtained when on day 0 the spleen cells were inoculated in 10 ml medium and the cultures left undisturbed until day 7). On day 7 the medium was changed completely. Foci were counted on unstained dishes on days 13–14 after infection. Titres are expressed in this and succeeding Figs as log₁₀ of the number of foci induced per 10⁷ inoculated spleen cells. In experiments not shown here we found that the number of foci that developed increased linearly and proportionally to the number of virus-producing spleen cells inoculated. Satellite foci did not occur in the dishes containing lower dilutions of the virus-producing spleen cells. Each circle represents an individual animal. ●, Male; ○, female. *a*, NZB (1–9 months); *b*, SWR (2–11 months); *c*, (SWR×NZB)F₁ (1–9 months); *d*, (NZB×SWR)F₁ (2 weeks); *e*, (SWR×NZB) F₁×NZB (3–5 months).

with cell-free filtrates from NZB mice[6], nor by transplanting NZB lymphomas[7] which are known to produce large numbers of virus particles[8]. Only spleen cells from old NZB mice can transmit the autoimmune disorder[6]. Transmission of the disease with cell-free extracts is unlikely to succeed because the NZB xenotropic virus cannot productively infect mouse cells; it can infect only cells of heterologous species[1,2]. Here we deal

with the vertical transmission of NZB viral genes as Mendelian traits—a phenomenon that has been demonstrated with other retroviruses[9]—to test the hypothesis that the development of autoimmunity in NZB mice and their crosses is independent of the expression of high titres of xenotropic viruses. We have found that the high grade expression of infectious xenotropic virus characteristic of NZB mice is a genetically determined trait. Two independently segregating loci seem to specify the NZB phenotype. So far, animals that are virologically like NZB have failed to develop signs of autoimmune disease.

Infectious xenotropic virus was measured by a modification[10] of the test described by Fischinger *et al.*[11]. Spleen cells from the test animal were cocultivated on monolayers of the 81 clone of the murine sarcoma virus-transformed CCC feline cell line (provided by Dr Peter Fischinger)[11]. Xenotropic viruses of various origins replicate in the 81 cell line and produce foci which are proportional in number to the input of virus-producing cells. This quantitative assay detected xenotropic viruses produced by cells of different mice, including BALB/c, B10.A, C57BL/6, AKR and C57L (Fig. 2 and unpublished observations). The assay reflected the virological status of the spleen cells on the day they were inoculated on the 81 cell line because mitomycin treatment of NZB spleen cells just before inoculation did not reduce the titre of xenotropic virus relative to that of untreated NZB spleen cells. Thus, the assay reflected the *in vivo* virological status (phenotype) of the animal, as was demonstrated in the case of ecotropic virus-producing strains[10].

Figure 1 shows the expression of xenotropic virus in two strains, NZB and SWR. As found by others[3,4], xenotropic virus was present in high titres in all the NZB mice (age range 1–9 months), whereas in none of the 25 SWR mice (2–11 months) could xenotropic virus be detected. It seems that the production of infectious xenotropic virus by SWR mice is either 'switched off' or proceeds at an extremely low rate. Alternatively, SWR mice may produce a defective virus. In any case, the 81 cell line assay clearly distinguished between NZB and SWR phenotypes: the former were uniformly positive in high titre and the latter uniformly negative.

Figure 1 also shows that all (SWR×NZB)F₁, (NZB×SWR)F₁ and (SWR×NZB)F₁×NZB backcross mice expressed high titres of xenotropic virus early in life. This indicates inheritance of the NZB virus phenotype by a genetic mechanism that is dominant, highly penetrant and contributed equally well by both sexes. No linkage to the sex of the animal was detected. We also tested the expression of infectious xenotropic virus in other crosses: (C57BL/6×NZB)F₁, (B10.A×NZB)F₁ and (AKR×NZB)F₁ (Figure 2). In all cases a picture similar to the (SWR×NZB)F₁ cross emerged—dominant, highly penetrant expression of the NZB viral phenotype.

Tests of the first backcross with SWR and the F₂ generations showed clearcut segregation that was independent of the maternal direction of the cross (Fig. 3). In the SWR backcross progeny, the ratio of virus-positive to virus-negative mice was

Table 1 Autoimmune markers and disease in NZB mice and their crosses with C57BL/6(B6), SWR and B10.A mice

Strain	Age (months)	Direct Coombs' test	Anti-DNA antibody		Nephritis
			Native	Denatured	
(B6×NZB)F₁ male	6–7		0/6	0/6	0/14
	9	0/9	0/14	0/14	0/14
(SWR×NZB)F₁ male	6–7		0/14	4/14*	0/18
	8	0/8	0/8	1/8*	0/8
(B10.A×NZB)F₁ male	8	0/4	0/4	0/4	0/13
female	7		0/7	1/7*	0/7
NZB male	8–12	6/8	3/8	8/8**	3/8
	3–5	0/7	0/7	7/7**	0/7

Direct Coombs' tests were carried out according to the method of Long *et al.*[15]. Antibodies to native and denatured DNA in the sera of the mice was quantified by the ¹⁴C DNA/glass filter technique developed by Lewis *et al.*[16]. Percentage binding of denatured DNA in the positive serum samples of the F₁ hybrids* was in the range 10–18% (mean 12%), whereas among the NZB mice** it was 14–36% (mean 25%).
Nephritis: degree of glomerular involvement was determined by histological criteria of Tonietti *et al.*[17], using haematoxylin–eosin and PAS-stained sections of kidneys.

approximately 3:1 (51:18, $P > 0.75$). This suggests two independently segregating loci either of which gave a positive phenotype. According to this interpretation, the virus-negative mice were the result of simultaneous homozygosity of recessive alleles to these two autosomal genes. Results obtained in the F_2 generation tended to support this interpretation, as a 15:1 ratio (54:4, $P > 0.9$) was obtained. So far, no linkage between coat colour and virus expression has been found. Linkage with other traits is being sought.

The quantitative data further support a multiple independent gene model because intermediate titres of virus (up to 150 focus-forming units (FFU)) were found in some mice of the backcross and F_2 generations. In contrast, all the F_1 mice expressed high titres of virus. The segregation ratios for high:intermediate:negative virus phenotype in the backcross and F_2 mice suggest that one of the NZB loci is responsible for high grade virus expression when present alone or in association with the other virus-inducing locus. Let us call the first locus NZV_1 and the second NZV_2 for convenience. The ratios suggest that when NZV_2 is present by itself, intermediate expression of virus would result. This hypothesis is being tested by crossing intermediate-titred mice with each other or with SWR mice to determine if the effect is caused by a segregating locus. If this is so, the hypothesis of phenotypic mixing between the NZB virus and a presumed defective SWR virus to give intermediate titres can be rejected. It is also conceivable that the high and intermediate titres are the result of two different types of NZB xenotropic viruses. This is being analysed.

The virological patterns in the various F_1 hybrids were quantitatively and qualitatively similar, indicating that no major genetic influences inhibited the expression of NZB virus. There was a minor effect in that $(B10.A \times NZB)F_1$ hybrids tended in general to have lower titres than the other two hybrids.

Although the data fit a two-locus model and are incompatible with a single-locus model, we cannot exclude that more than two virus-inducing loci are segregating. If there were one locus with high penetrance and several other loci with low penetrance, the overall segregation ratios might mimic a two-locus pattern. Further studies of backcross families will clarify this point.

We cannot state whether the postulated NZB loci are genetic elements of the virus itself or are genes that promote the expression of the virus. The distinction between these alternatives requires the use of genetic markers that distinguish

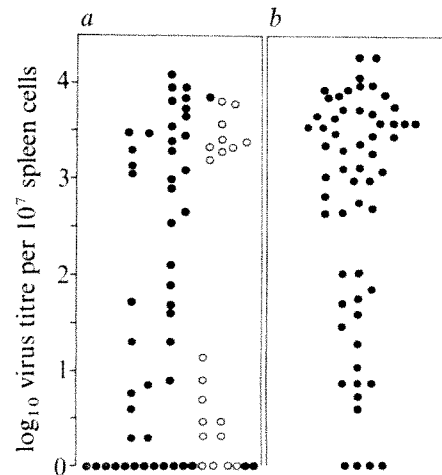

Fig. 3 Xenotropic virus titres in mice of first backcross with SWR and the F_2 generations. All mice were 3–4 months old. a: ●, SWR × (SWR × NZB)F_1; ○, (SWR × NZB)F_1 × SWR. b, (SWR × NZB)F_2.

between subtypes of xenotropic viruses (for example, NZB-xenotropic virus, or MuLV-x$^\beta$, and C57BL/6-xenotropic virus, or MuLV-x$^\alpha$)[12]. It is likely that we are not dealing with either the presence or absence of genetic information required for the phenotype under study since the low virus strains C57BL/6, B10.A and AKR obviously can make xenotropic virus; and the SWR mouse, although 'virus negative' when tested in the 81 (cat) and A673 (human)[13] cell lines, is known to have the p12 of xenotropic virions in its cells[13].

Table 1 shows the results of preliminary studies for autoimmune disease in NZB mice and their crosses with SWR, C57BL/6 and B10.A mice. Markers of autoimmunity were readily detected in NZB mice. In contrast, these abnormalities were either absent or infrequent in all of the F_1 crosses tested, although all the animals expressed high titres of xenotropic viruses from an early age. These data do not take into account the possibility that autoimmune markers or autoimmune disease may develop later in the F_1 hybrids than in the NZB parent. This time-dependent phenomenon has been noted by others and is a complicating feature of genetic analysis of autoimmunisation in NZB mice and their crosses[14]. Since the material required for virological analysis was obtained in all of the mice by biopsy of the spleen, these animals are currently being aged and will be retested for signs of autoimmunisation at a later time. It will also be of interest to note if the virus-negative backcross and F_2 progeny develop autoimmune disease later in life. Such a finding would support the hypothesis that the autoimmune abnormalities of NZB mice are independent of xenotropic viruses.

Sex differences in formation of anti-T-cell antibodies

A NATURALLY occurring thymocytotoxic autoantibody (NTA) has been found in significant titre early in life in NZB mice[1]. This antibody is present in almost all NZB mice by 3 months of age, and is associated with an age-dependent loss of T cells in these mice[2-4]. NTA may be responsible for an initial loss of suppressor T cells in NZB mice and thereby contribute to the development of autoimmunity. Although other mouse strains (NZW, C57BL/6J, AKR/J, BALB/cJ, and 129) may produce NTA later in life, the prevalence and titre of NTA is much lower than in NZB mice. NTA reacts with brain- and thymus-derived cells as well as thymocytes, but not B cells or non-lymphoid abdominal organs[1-5]. In contrast to standard anti-θ serum, NTA can combine with both Thy 1.1 (θ-AKR) and Thy 1.2 (θ-C3H)[1,6]. Genetic factors have been implicated in the development of autoimmunity in New Zealand mice[7,8]. In addition, X-linked immune response genes have been described for synthetic[9] and naturally occurring[10] nucleic acids. Moreover, female hybrids (NZB/NZW) develop a more severe disease than males. We therefore undertook the present study to determine the contribution of the X chromosome to the development of NTA.

Hybrid mice were produced by crossing NZB/N and DBA/2 strains. The DBA/2 strain was chosen because of the reported lack of warm-reacting NTA at approximately 1 yr of age[2]. Since the presence of NTA in high titres occurs earlier in the life of NZB than in other strains, 12-month-old hybrid mice were chosen for study so that differences in the formation of NTA would not represent time differences alone, but genetic background as well. Because the X chromosome of the NZB strain may be important in determining the presence of NTA, we wished to rule out a simple hormonal mechanism. To study this (DBA/2 × NZB/N) and (NZB/N × DBA/2)F₁ hybrid virgin mice of both sexes were castrated at 5 weeks of age[11], with littermates left intact. Sera obtained at 1 yr of age were studied for the presence of NTA as described previously, with only minor modifications[6]. Briefly, thymocytes from 4–6-week-old C57BL/6N were incubated with 30 μCi ⁵¹Cr per 10⁷ cells for 30 min at 37 °C. Labelled thymocytes (5 × 10⁴) were added to 50 μl of serially diluted test serum and incubated for 30 min at room temperature followed by 30 min at 4 °C. Cells were

spun, washed twice and incubated with 50 μl 1:15 rabbit complement (previously absorbed with C57BL/6N thymocytes) for 30 min at 37 °C. The suspension was then centrifuged and 50 μl of supernatant removed and counted. The positive control was a pool of NZB sera with known NTA activity; the negative control consisted of sera from 1-yr-old female DBA/2 mice. Maximum ⁵¹Cr release was obtained by freeze-thawing, and cytotoxicity of complement (C) alone determined. Percentage cytotoxicity was calculated as

$$\frac{(\text{c.p.m. test serum} - \text{c.p.m. C})}{(\text{c.p.m. freeze-thaw} - \text{c.p.m. C})} \times 100$$

All sera were assayed in duplicate with good reproducibility. The cytotoxic titre was the last dilution giving greater than 50% ⁵¹Cr release. A positive titre was at least 1:4.

Approximately half of the unmanipulated female NZB × DBA mice had NTA at 1 yr of age, whereas none of the males was positive (Table 1). Castration of the females did not affect the percentage positive or the titre of NTA. Castration of the males at 5 weeks of age, however, led to NTA formation indistinguishable from that of females (Table 1).

DBA-mothered F₁ hybrids had a lower incidence of NTA than corresponding NZB-mothered mice. Nevertheless, the same pattern of NTA incidence was observed. Hybrid males failed to produce NTA unless they were castrated.

The studies of uncastrated mice demonstrate NTA formation in female but not male F₁ hybrids. Superficially, the results for the DBA-mothered F₁ hybrids might suggest a role for an immune response gene carried on the NZB X chromosome, but not the DBA X chromosome. This would be in agreement with a previous study of the anti-DNA response[10]. According to this model, NZB-mothered F₁ males would receive a 'responder' X chromosome and produce NTA. We found, however, that NZB-mothered F₁ males failed to produce NTA, indicating a mechanism other than an X-linked immune response gene. Moreover, the observation that castration abolished the difference between hybrid males and females, suggested a sex hormonal mechanism. Thus, the lack of NTA in male NZB hybrids is due in part to a functional testis; the possibility that male sex hormones are responsible is under investigation. It is not clear why NZB males develop NTA. They are relatively infertile and may have a deficiency in suppressive male sex hormones. Alternatively, additional factors (such as a more rapid loss of suppressor cells than occurs in NZB/DBA male F₁ hybrids) may operate to make it possible for them to develop NTA. In addition, both NZB male and female mice share similar severity of disease manifestations unlike the NZB/NZW F₁ model where females clinically have a more severe expression of autoimmunity[8,11].

The data reported here provide a possible explanation for the female predominance in both murine and human autoimmunity. Male sex hormones may inhibit the production of certain autoantibodies; therefore, males would be protected from the development of autoimmunity. The study of such a mechanism may lead to a better understanding of autoimmunity as well as potential therapeutic intervention.

Serum containing endotoxin-induced tumour necrosis factor substitutes for helper T cells

WHEREAS immunocompetent precursor B cells recognise antigenic determinants by way of specific surface receptors (an interaction which presumably initiates cell division[1,2]), the binding of antigen to surface receptors alone does not result in the differentiation of B cells to antibody-secreting cells. To accomplish this differentiation step a second signal is needed. This signal may be provided by T cells in the form of a soluble factor which they produce *in vitro* after contact with antigen[3-5]. Besides T cells, activated peritoneal macrophages have also been shown to produce a factor which allows B cells from athymic Nu/Nu mice to produce antibody against fowl gammaglobulin *in vitro*. Production of this factor is increased by addition of bacterial lipopolysaccharide (LPS) to the culture medium[6]. LPS itself has been shown to provide the second signal (antigen being the first) for antibody production by B cells[7], but it is not clear whether the effect on antigen-reactive B cells is direct, or mediated by other cells. We report here that injection of LPS, in certain conditions in the mouse, induces the release of factors into the serum which enable B cells to produce antibody to heterologous red-cell antigen *in vitro* in the absence of helper T cells. The factor is released in large quantity when LPS is injected into mice that have been primed with BCG. It is hardly, if at all, detectable in the serum of mice injected with LPS but not pretreated with BCG. Our investigation was prompted by the discovery that serum from BCG-infected mice given LPS causes acute necrosis of established tumour grafts in syngeneic mice (tumour necrosis serum, TNS)[8]. After partial purification, tumour-necrotising activity was shown to reside in a glycoprotein fraction (termed tumour necrosis factor, TNF) with a molecular weight of about 150,000 that migrates with the α-2-globulins[9].

TNS used in the experiments reported here was produced in CD-1 Swiss mice. Twenty million living BCG organisms (Trudeau Institute, Saranac Lake, New York) were injected intravenously, followed by intravenous injection of 25 μg LPS (Difco) at the peak of hepatosplenomegaly, usually 2 weeks later. The mice were exsanguinated 2 h after injection and their serum separated and passed through a Millipore filter before use in tissue culture.

The production of haemolytic antibody by spleen cells from BDF[1] mice was studied in the Mishell–Dutton culture system[10]. Initial experiments showed that the production of antibody to sheep red blood cells (SRBCs) by unfractionated spleen cells was accelerated and augmented by addition of TNS or TNF to the culture medium (Table 1). This led to the question of whether TNF acted directly on B cells, or indirectly through macrophages or T cells. Experiments with fractionated spleen cells were therefore carried out. After removal of macrophages by passage through Sephadex G-10 columns[11] the spleen cells failed to produce antibody to SRBCs. Responsiveness was restored by addition of 5 × 10⁻⁵ M 2-mercaptoethanol (2-ME)[12], but not by addition of TNS. In Sephadex-treated cultures supplemented with 2-ME, addition of TNS enhanced the generation of antibody-forming cells (Fig. 1). As the *in vitro* response to SRBCs requires the participation of helper T cells, experiments were carried out to determine the effect of TNS on T-cell-depleted populations. Spleen cells which had been depleted of T cells by treatment with anti-Thy-1.1 serum and complement (after passage through Sephadex G-10 columns) produced only few plaque-forming cells (PFCs) in culture; the production of antibody to SRBCs by the macrophage
Fig. 1 Restoration of antibody production by macrophage-, and T-cell-depleted spleen cell cultures with TNS. PFC response on days 3(*a*) and 4(*b*). Each point is the average of 2 cultures. ●, 2-ME not added; ○, 2-ME added; ▲, 2-ME added, T cells removed by treatment with anti-Thy-1.1 and rabbit complement; △, 2-ME added, cells treated with rabbit complement (control).

and T-cell-depleted spleen cell population was restored by addition of TNS to the culture medium (Fig. 1).

Figure 2 shows results of experiments with congenitally athymic Nu/Nu mice. Since they lack helper T cells, spleen cells from these mice do not produce antibody to red blood cells *in vitro*. Addition of TNS to the culture medium permitted a response (of the same magnitude as that of spleen cells from littermate Nu/+ mice which do not lack T cells) to the antigen that was used to sensitise the cultures (burro red blood cells, BRBCs), but not to an unrelated antigen (SRBC). Addition of TNS was effective even if delayed as long as 2 d (Table 2), and this was also true for TNF. Thus, injection of LPS into BCG-infected mice causes release of a factor which can substitute for helper T cells in the production of antibody to heterologous red-cell antigen *in vitro*, an activity which

Fig. 2 Restoration of antibody production by spleen cells from Nu/Nu mice with TNS. Cultures (in MEM + 5% FCS) were immunised with BRBC. Anti-BRBC (*a*) and anti-SRBC PFC (*b*) were assayed on day 4. △, TNS; ●, normal mouse serum; ○, serum from mice treated with BCG only; □, serum from mice treated with LPS only.

Table 1 Effects of TNS on production of antibody to SRBCs in vitro

| Addition to culture*	Anti-SRBC PFCs per culture	
	Day 3	Day 4

Fig. 3 Induction of antibody production in cultures of CR⁻ spleen cells by TNS. Spleen cells were passed through Sephadex G-10 columns coated with complement-reacted antigen-antibody complexes (CR⁻ spleen cells, hatched bars) or uncoated Sephadex G-10 columns (CR⁺ spleen cells, open bars) TNS was added at 1% final concentration As source of macrophages (Mφ), 5 × 10⁴ peritoneal cells were added to the cultures. Average of 2 cultures

resides in the same serum fraction (TNF) as the tumour-necrotising activity

We have already indicated that TNS does not substitute for that function of macrophages which can be replaced by 2-ME. We have described another function of macrophages, namely, the support of antibody formation in vitro by mouse spleen cells which are depleted of B cells carrying complement receptors (CR⁺)[13]. CR⁻ spleen cells are incapable of cooperating with primed helper cells in culture unless macrophages are present. In this context, macrophages cannot be replaced by 2-ME, but they can be replaced by culture supernatants of peritoneal macrophages that have been activated in vivo by injection of BCG. We have now found that TNS induces CR⁻ spleen cells to produce antibody to SRBCs and to cooperate with primed helper cells.

CR⁻ spleen cells were obtained by passage of mouse spleen cells through Sephadex G-10 columns coated with complement-reacted antigen–antibody complexes. This type of column removes macrophages and CR⁺ B cells[13]. As a control, spleen cells were passed through uncoated Sephadex G-10 columns, which remove macrophages[11], but not CR⁺ B cells[13]. CR⁻ spleen cells from mice primed with SRBC were used as a source of pri,ed helper T cells[14]. One part primed cells (depleted of CR⁺ cells) was mixed with 9 parts unprimed CR⁻ cells, the cultures were sensitised with trinitrophenyl (TNP)-conjugated SRBCs, and the number of anti-TNP PFCs was determined on day 4. As shown in Fig 3, CR⁻ spleen cells not only generated considerably less anti-TNP PFCs than CR⁺ spleen cells, but also failed to cooperate with SRBC-primed helper T cells. TNS induces CR⁻ spleen cells to produce antibody and to cooperate with primed helper T cells in the absence of macrophages. We have postulated[13] that CR⁻ B cells must differentiate into CR⁺ B cells to carry out this function. This step in B-cell differentiation may be induced by macrophages when they are activated as, for example, after injection of BCG or by activated helper T cells[13]. As we will report elsewhere, TNF induces differentiation of CR⁻ B cells to CR⁺ B cells in vitro (M.H. and U Hammerling, unpublished).

The cellular origin of TNF is not as yet known. For various

reasons, macrophages have been considered a likely source[8,9]. The most striking phenomenon which occurs during the priming phase for TNF production is proliferation and activation of macrophages. Moreover, activated macrophages or culture supernatants of activated macrophages have been reported to possess activities that are similar to those of TNF. Like TNF they induce antibody formation in cultures of spleen cells from Nu/Nu mice, particularly after exposure to LPS. In addition, macrophages exposed to LPS become cytotoxic for transformed target cells in tissue culture[15,16], and TNF shares this property[8] Some effects of TNF, on the other hand, mimic effects of factors assumed to be derived from T cells. As these T-cell factors have been reported to react with antisera directed against Ia and β_2 microglobulin[5], use of such antisera may be useful for further definition of TNF. Until TNF has been fully characterised, however, it would be premature to ascribe the immunological effects reported here to the anti-tumour factor

Table 2 Substitution of T-cell helper function by simultaneous as well as delayed addition of TNS or TNF

Additions	Anti-SRBC PFCs per culture on day 4	
	(addition on day 0)	(addition on day 2)
None	<5	<5
TNS	170	390
TNF	230	310

Cultures of spleen cells of Nu/Nu mice were immunised with SRBCs on day 0 and assayed for anti-SRBC PFCs on day 4 TNS 1%, or TNF 0 13 mg ml⁻¹, were added as indicated on day 0 or day 2. Each value is the average of 3 cultures.

Dissociation of alcohol tolerance and dependence

CHRONIC.intoxication with ethanol has been shown to result in tolerance to and physical dependence on this drug[1,2]. In general, the development of tolerance and physical dependence during intake of addictive compounds have been looked on as inexorably linked phenomena produced by a common biochemical[3] or physiological[4] mechanism. This was supported by the studies of Way et al.[5] who demonstrated a simultaneous development and disappearance of tolerance and physical dependence after morphine pellet implantation in mice. We were interested in the possible application of the same theoretical framework to the development of tolerance to and physical dependence on ethanol. Previous work[6,7] demonstrating changes in noradrenergic systems in brain after chronic treatment led us to study the effect of 6-hydroxydopamine (6-OHDA) pretreatment on the development of tolerance to and physical dependence on ethanol.

In our studies, one group of C57BL/6 male mice was injected intracerebroventricularly[8] with 6-OHDA (50 µg in 10 µl artificial cerebrospinal fluid (CSF)[9] containing 5 mg ml^{-1} ascorbate), a second group of mice was injected with only the artificial CSF with ascorbate, and a third group of animals received artificial CSF containing no ascorbate. Since the presence of ascorbate in the artificial CSF had no effect on any of the parameters discussed below, all reported comparisons were between groups of animals injected with the CSF containing ascorbate and those injected with CSF, ascorbate and 6-OHDA. Brain levels of dopamine[10], noradrenaline[10] and 5-hydroxytryptamine (5-HT)[11] were determined in aliquots of two pooled brains[8,12] seven days after the intracerebroventricular injection and then again after chronic ethanol treatment. These levels were 6.47 ± 0.87, 1.47 ± 0.29 and 3.24 ± 0.48 nmol per g brain, respectively for the animals injected with 6-OHDA and 8.88 ± 1.60, 3.26 ± 0.46 and 3.44 ± 0.29 nmol per g brain, respectively for those injected with artificial CSF. The levels of these neurotransmitters were not significantly altered by the chronic ethanol treatment described below.

A week after the injection, mice were placed in individual cages and offered a liquid diet consisting of Carnation Slender, sucrose (100 g l^{-1}) and Vitamin Diet Fortification Mixture (ICN Pharmaceuticals) (3 g l^{-1}) as their only food source. Twenty-four hours after being placed on the liquid diet, mice were divided into four groups:

Group 1: animals injected with artificial CSF. This group continued to receive the sucrose-containing diet throughout the period when the other animals (groups 3 and 4) received ethanol.

Group 2: mice injected with 6-OHDA and continued on the diet containing sucrose as were those in group 1.

Group 3: mice injected with artificial CSF. These mice were fed a diet in which the sucrose was substituted with 7% v/v ethanol.

Group 4: mice injected with 6-OHDA and fed the diet containing the 7% v/v ethanol as were those in group 3. Animals were maintained on their respective diets for seven full days, and on the morning of day 8, all animals again received the diet containing sucrose (withdrawal). During the period that mice received ethanol, body weight, behavioural intoxication, body (rectal) temperature, quantity of diet consumed and blood ethanol levels[13] were monitored daily[14]. The quantity of diet given to the mice consuming the sucrose-containing mixture was made equal to the amount of ethanol-containing diet consumed by the animals in groups 3 and 4.

No differences were found in the daily amounts of diet consumed or blood ethanol levels during the chronic treatment with ethanol between animals in group 3 compared with those in group 4 (t test, $P > 0.25$). Behavioural intoxication scores[14] were also not significantly different between these two groups

of animals. Body temperature was, however, found to be lower in animals of group 4 compared with those of group 3 (t test, $P < 0.05$) during the last two days on the ethanol diet. A more complete description of the animals during the period of chronic ethanol intake will appear elsewhere (Ritzmann and Tabakoff, in preparation).

After withdrawal from ethanol, animals were observed over a 12-h period: six 1-h periods of observation alternating with 1-h periods during which no observation took place. During the observation periods, body temperature was measured and behavioural signs of withdrawal were noted[14]. Withdrawal signs were scored as follows: 0 = no withdrawal symptoms; 1 = characteristic tremors and spasms when mice are lifted by the tail[15]; 2 = spontaneous tremors and spasms; 3 = spontaneous seizures (clonic and/or tonic)[14]; and 4 = death.

The behavioural withdrawal scores and measures of the concomitant hypothermia[14] are summarised in Table 1. No significant differences (see legend to Table 1) in either the severity of the hypothermia or the behavioural manifestations of withdrawal were evident when animals from groups 3 and 4 were compared. Animals receiving the sucrose-containing
Fig. 1 Body temperature and sleep time after ethanol. Mice were injected intraperitoneally with ethanol (3, 4 and 5 g kg^{-1}) 26 h after withdrawal, and sleep time (a) and body temperature (b) were monitored. Since no differences in these parameters or blood ethanol levels were found between animals in groups 1 and 2, the values obtained with these animals were pooled and are labelled "control." Sleep time represents the time from loss of righting reflex to the time the mouse could right itself twice in 30 s. The bars represent the mean$\pm$s.d., and the number within each bar is the number of animals used for the determination. Rectal temperature was monitored at 15- and 30-min intervals for 3 h after ethanol injection. The bars represent the mean$\pm$s.d. of the greatest change from preinjection temperatures recorded during this period. The nadir for the 3 and 4 g kg^{-1} dose occurred at 30 min and for the 5 g kg^{-1} dose at 60 min after injection. Comparison between groups at each dose was made using the t test as well as the Mann–Whitney U test. *Groups significantly different from each of the other groups ($P < 0.05$) at a particular dose; other groups were not significantly ($P > 0.2$) different from one another.

Table 1 Hypothermia and withdrawal symptoms in mice

Behavioural withdrawal score	Time after withdrawal (h)					
	0	2	4	6	8	10
Group 3:						
0	36.2±0.4 (n = 10)	36.±0.4 6 (n = 9)	36.1±0.1 (n = 2)	—	36.9±0.2 (n = 4)	36.9±0.4 (n = 11)
1	—	35.0 (n = 1)	35.1±0.7 (n = 6)	35.8±0.6 (n = 6)	35.9±0.6 (n = 6)	36.0 (n = 1)
2	34.0 (n = 1)	34.2 (n = 1)	34.6±0.3 (n = 4)	34.2±0.7 (n = 6)	35.7±0.1 (n = 2)	—

0	35.3±0.4 (n = 12)	36.5±0.5 (n = 11)	36.4 (n = 1)	36.4 (n = 1)	36.9±0.1 (n = 2)	36.6±0.5 (n = 8)
1	—	35.8 (n = 1)	35.1±0.7 (n = 6)	35.5±0.5 (n = 5)	36.3±0.9 (n = 4)	35.8±1.2 (n = 3)
2	—	—	34.3±0.6 (n = 4)	34.4±0.4 (n = 4)	35.1±0.9 (n = 5)	—
3	—	—	—	34.8 (n = 1)	—	—
4	—	—	(n = 1)	—	—	—

Ethanol was removed from the diet of mice after 7 d of chronic consumption, and behaviour and body temperature were monitored. Mice receiving similar withdrawal severity scores at the various times of testing were grouped and the mean ± s.d. of the body temperature for each such group was determined and noted in the table. n represents both the number of animals exhibiting the particular withdrawal symptoms at the time of testing and the number of animals used to determine the mean temperature for the group. Hypothermia occurring in groups 3 and 4 was compared, after pooling the temperature values at each time point, using Student's t test. To assess whether or not behavioural withdrawal scores were different between groups 3 and 4, mice were subdivided as those receiving a score of 0 or 1 and those receiving a score of 2 or higher at each time point. Statistical analysis was performed using the Fischer Exact Probability test. No statistically significant differences were found between the body temperatures or withdrawal scores of groups 3 and 4.

control diet (groups 1 and 2) demonstrated none of the withdrawal symptoms. In separate experiments withdrawal hyperexcitability was assessed by injecting animals with pentylenetetrazol (60 mg kg^{-1}, intraperitoneally) and monitoring the incidence of convulsive seizures and death occurring within a 30-min period following such injection[16]. Pentylenetetrazol was administered to animals between 6 and 7 h after withdrawal of ethanol.

Animals which had been withdrawn from the ethanol-containing diets were significantly (binomial test[17]; P in all cases < 0.025) more susceptible to pentylenetetrazol-induced convulsions than sucrose-fed controls. No statistically significant differences (P > 0.3) in severity or frequency of pentylenetetrazol-induced seizures were, however, noted when comparing animals of group 3 with those of group 4. Eight animals from each of the four groups were tested, and the number of animals exhibiting clonic or tonic convulsions or dying in seizures after treatment with pentylenetetrazol in group 1 was two; in group 2, two; in group 3, six, and in group 4, seven.

Twenty-six hours after withdrawal, when all overt signs of the withdrawal syndrome were no longer present, mice were injected intraperitoneally with ethanol and "sleep time"[18] and rectal temperature were monitored. Mice previously injected with pentylenetetrazol were not used in these studies.

Animals of group 3 were found to be tolerant to the effects of ethanol by measures of both rectal temperature and "sleep time" (Fig. 1). On the other hand, pretreatment of the animals with 6-OHDA before the chronic ethanol treatment (group 4) resulted in a block in development of tolerance to the measured effects of ethanol (Fig. 1). No significant differences in blood ethanol levels during the time that behavioural and physiological parameters were being measured were evident between any of the groups after injection of ethanol (3 g kg^{-1}).

Thus, animals treated with 6-OHDA and force fed a diet containing ethanol were found to become physically dependent on ethanol (as demonstrated by the appearance of withdrawal symptoms), but did not become tolerant to two of the major physiological effects of ethanol administration, that is, hypothermia and sedation.

Administration of 6-OHDA has been shown to result in the

destruction of catecholamine-containing neuronal terminals[19]. Such destruction of the functional connections between the noradrenergic neurones and other brain neurones seems to prevent the necessary alterations in neural cybernetics which produce tolerance after chronic ethanol treatment. Although the injections of 6-OHDA did not produce a statistically significant (t = 1.87, d.f. = 6) decrease in the levels of dopamine in our mice, the levels were substantially altered. Thus, we do not feel that the block in the development of tolerance can at present be totally ascribed to the destruction of only the noradrenergic systems.

The dissociation of tolerance and physical dependence witnessed in the present study provides an important conceptual framework within which the neurological effects of ethanol should be viewed. Seevers and Woods[20] and Kissin[21] suggested previously that tolerance and physical dependence may not necessarily be unitary phenomena, and our studies demonstrate that certain manifestations of tolerance to ethanol may be eliminated without affecting the development of physical dependence produced by this drug.

Progressive glomerulonephritis in mice treated with interferon preparations at birth

IN addition to the well known antiviral action[1] interferon preparations exert various biological effects on cells (for references see refs 2 and 3). While investigating the effect of interferon on the growth and development of newborn mice, we found that daily injection of potent mouse interferon preparations resulted in extensive liver cell degeneration and death between days 8 and 14 (ref. 4). When interferon treatment, begun at birth, was stopped between days 6 and 8 of life, liver cell damage appeared to be reversible and most mice recovered. In the ensuing months, several of these mice died and although the liver and other organs appeared normal, the kidneys were pale and the surface was granular. Histological examination revealed a severe glomerulonephritis. We report here an investigation of this phenomenon.

Newborn Swiss (and in one experiment C3H mice) from specific pathogen-free colonies were injected subcutaneously in the interscapular region with 0.05 ml of mouse interferon or the different control preparations daily from day 0 to days 6–8, at which time treatment was stopped. When interferon-treated mice were killed on day 8, histological sections of liver showed focal cellular necrosis, as reported before[4], but the kidneys appeared normal. Nevertheless, Swiss mice began to die with renal lesions as early as day 35. Autopsy of some mice dying with kidney disease showed signs suggestive of cardiac failure, that is enlarged heart, and haemorrhagic and oedematous lungs.

Mice were killed at regular intervals, and sections of organs were examined under light microscopy. In all cases, the kidneys of Swiss mice treated with interferon at birth showed glomerulonephritis (Table 1) whereas the liver appeared normal. The kidney pathology can be summarised as follows. In "early" lesions (Swiss mice killed on the 20th day of life, Table 1) the glomeruli appeared moderately enlarged with some thickening of the mesangium, some segmental foci of mesangial proliferation and some thickening of peripheral capillary loops. There were no tubulo-interstitial lesions except for a few mononuclear cells. The vessels appeared normal. By immunofluorescence there were focal and segmental granular deposits of IgG, IgM and C3 in the mesangial spaces and along some glomerular basement membranes (GBM). Fibrinogen and IgA were not detected. In Swiss mice killed after 31 d, the lesions were more conspicuous with hyalinisation of glomerular tufts (with epithelial crescents and voluminous subendothelial deposits) (Fig. 1a). In well advanced disease, virtually all glomeruli were sclerotic. Amyloid was not detected. The tubulo-interstitial lesions paralleled the glomerular damage, showing extensive sclerosis, and diffuse atrophy of tubules with dilated lumina filled with hyalin and proteinaceous casts (Fig. 1b). By immuno-

Mouse interferon was prepared from Swiss mouse C-243 cells induced with Newcastle disease virus (NDV), and concentrated, partially purified and assayed as decribed before[5]. Mock interferon was prepared in a manner identical to that used in the preparation of interferon with the exception that the interferon inducer, NDV, was either omitted, or added for 1 h immediately before collection of the culture supernatant. All interferon and control preparations were dialysed further for 24 h at 4 °C against 0.01 M perchloric acid before testing for toxicity on a line of L 1210 cells resistant to interferon[6]. The specific activity of mouse C-243 cell interferon preparations was in the range 0.7–3.0 × 10⁶ U per mg protein. In one experiment mice were treated with a more purified C-243 interferon preparation (1.9 × 10⁷ interferon reference U per mg protein) (purified by affinity chromatography using sheep anti-mouse interferon globulins). C-243 cell control preparations contained approximately the same amount of protein per ml as the C-243 cell interferon (that is 1.5–3.4 mg ml⁻¹). Partially purified human interferon (specific activity 3.5 × 10⁵ U per mg of protein) prepared in leukocyte suspensions inoculated with Sendai virus was provided by Dr K. Cantell[7]. Mouse interferon units quoted are as measured in our laboratory and one of our units equals 4 mouse interferon reference units.
* A different mouse C-243 cell interferon preparation (titre 1:800,000 to 1:1,600,000) was used in each experiment. Only mice having been injected daily from birth to days 6 to 8 of life are included.
† Mouse C-243 interferon with a titre of 1:800,000 was heated at 60 °C for 2 h at pH 10. Residual titre was 1:20.
‡ Titre of human leukocyte interferon was 1:1,000,000 (MRC reference interferon 69/19 U) as assayed on human diploid fibroblasts.
§ No. of mice with histological confirmation of glomerulonephritis per total number of mice killed. Each kidney was examined by light microscopy and the severity of lesions was graded on a scale from 0 to 4. In all cases there was little variation in the extent of lesions within a given series and the figures in brackets indicate the mean index of severity of kidney lesions for each series.
¶ The kidney of one mouse showed glomerulonephritis grade 2.
‖ The kidneys of two mice showed glomerulonephritis grade 1.

Fig. 1 Kidneys of Swiss mice treated with mouse interferon for the first 7–8 d of life. *a*, Mouse killed at 100 d. Note mild glomerular proliferation and hyalinisation of glomerular tufts. Tubular epithelium appears flattened with dilatation of lumina. There are a few inflammatory cells in the interstitium (×250). *b*, Mouse killed at 60 d. Note extensive sclerosis of interstitial tissue (with cellular infiltration) with pronounced atrophy of tubules and sclerotic glomeruli (×100). *c*, Mouse killed at 85 d. Stained with fluoresceinated anti-mouse IgG serum. Note coarse granular deposits along GBM (×540). *d*, Stained with fluoresceinated anti-mouse C3 serum. Note deposits of C3 along GBM. The deposits of C3 along the tubular basement membrane have no pathological significance as they are also present in control mice (×400). Renal tissue was fixed in Dubosq–Brazil fixative (alcoholic Bouin) for 2 d and then in 4% formalin in saline, and cut at 3 μm. The following stains were used systematically: Mallory's trichromic, periodic acid-Schiff, haematoxylin and eosin, Weigert's fuchsin, Wilder's reticulin and crystal violet. Immunofluorescence was done on snap-frozen specimens cut in a cryostat. Rabbit anti-mouse IgG, IgA, IgM, C3 and fibrinogen sera were obtained from Cappell Laboratories. The specificity of each antiserum was checked by immunoelectrophoresis. All magnifications are original magnifications.

fluorescence there were granular coarse deposits of IgG, IgM and C3 along the GBM (Fig. 1*c* and *d*). Fibrinogen was detected in crescents. IgA was not detected.

The results of our experiments can be summarised as follows. (1) In nine experiments, all Swiss (60 out of 60) mice treated with potent interferon preparations for the first 6–8 d of life developed severe glomerulonephritis early in life (Table 1). Only one out of 86 mice treated with the various control preparations and two out of 65 untreated mice developed a moderate glomerulonephritis and this occurred only in mice kept for more than 143 d (Table 1). (The finding of glomerulonephritis in some ageing Swiss mice is in accord with the results of Oldstone and Dixon who reported a "mild nephritis seen in 7% of SWR/J control mice by 9 months"[8].)

(2) Glomerulonephritis developed only in mice inoculated with enough interferon and for a sufficient time. Thus, only mice inoculated with interferon preparations titering approximately 1 : 10^6 for 6–8 d developed glomerulonephritis. Mice injected for 8 d with interferon preparations of lower titre, that is 1 : 10^5 (23 mice), or 1 : 10^4 (18 mice), showed no signs of glomerulonephritis when killed at 85, 140 and 198 d. In addition, injection of potent interferon preparations (1 : 10^6) did not result in glomerulonephritis when injected for only the first 2 d of life (20 mice killed at 85, 140 and 198 d).

(3) Interferon treatment resulted in glomerulonephritis only when administered during the first week of life. Thus, none of nine mice inoculated between the 8th and 15th d of life with an interferon preparation titering 1 : 10^6 showed glomerulonephritis when killed at day 59. (4) Male and female mice seemed to be equally susceptible as judged by the severity of disease and the incidence of death.

(5) The progression of the disease in Swiss mice was observed by killing mice at intervals and by following the progression of lesions in the same mouse after unilateral nephrectomy. Kidney lesions were minimal at 3 weeks, definite at 1 month and considerably more advanced in the ensuing weeks. (Table 1: note figures in brackets indicating mean index of severity of kidney lesions graded on a scale from 0 to 4). A kidney from each of two interferon-treated mice was removed on day 31 and the mice were killed on day 45 and 60. In both cases a progression of lesions in the remaining kidney was observed. (Unilateral nephrectomy in control mice did not cause glomerulonephritis in the contralateral kidney.) Since a number of interferon-treated mice died (probably of renal failure) after 4 weeks of life, it is possible that the apparent decrease in the severity of kidney lesions in mice older than 102 d (Table 1) reflects the selection of surviving mice with less severe disease rather than a reversibility of the pathological process.

(6) Although glomerulonephritis also developed in C3H mice treated from birth for 6–8 d with mouse interferon preparations titering 1 : 10^6 (according to the protocol used for Swiss mice) (Table 1), the glomerular lesions appeared

to be less severe than in Swiss mice at the same age, and deaths were not observed. Kidneys of eight out of eight C3H mice killed at 43–55 d showed moderate glomerulonephritis (Table 1). At 104–132 d, although glomerular lesions were present in six out of nine mice, these were less marked than in mice killed earlier. Furthermore, a kidney biopsy, at 45 d, of an interferon-treated C3H mouse showed moderate disease, whereas only minimal lesions were present when this mouse was killed at 104 d. Thus the glomerulonephritis in C3H mice is not only less severe than in Swiss mice, but may be reversible. (It is interesting in this regard that C3H mice developed a less severe glomerulonephritis than SWR/J mice when infected transplacentally or neonatally with lymphocytic choriomeningitis virus[*].)

Because there was a lapse of several weeks between cessation of interferon treatment (days 6–8) and the appearance of glomerulonephritis (day 20), and as interferon is cleared rapidly from the circulation[10-13], it seems unlikely that the development of progressive nephritis was due to a local retention of interferon. It is possible, however, that interferon damaged the kidney during the first week of life directly, or indirectly perhaps through its toxic effect on the liver[4,14]. Alternatively, this treatment might have altered the maturation of the kidney or some other organ(s), such as the spleen[4], leading ultimately to the development of glomerulonephritis.

The rapidity of onset of the glomerulonephritis and the histological lesions themselves do not permit ready classification in terms of pathogenesis[15-19]. The absence of linear deposits of Ig argues against the hypothesis of an anti-GBM glomerulonephritis and anti-GBM antibodies were not present in the sera of sick mice tested by indirect immunofluorescence. The granular pattern of the Ig and C3 deposits seem to favour the hypothesis of an immune complex nephritis, although we have no idea about the nature of a hypothetical antigen. We have never detected neutralising antibody to interferon in either the serum or γ-globulin-containing eluates of the kidneys of interferon-treated mice (neither was interferon itself present in these eluates), nor is there any evidence to suggest that interferon treatment during the first week of life activates a latent virus[4]. Anti-DNA antibodies were also not detected in the serum of sick mice.

Several chronic virus infections in animals can result in the late development of nephritis which is associated with the progressive deposition of virus–antibody complexes in the glomerulus[20-22]. Perhaps some of these viruses induce interferon in the neonatal period, contributing to the further development of glomerulonephritis. Furthermore, if our results in mice can be extrapolated to man, they suggest that an acute virus infection of the human newborn, if associated with the production of sufficient interferon, might result later in life in the development of a progressive glomerulonephritis.

Postponement of symptoms of hereditary muscular dystrophy in chickens by 5-hydroxytryptamine antagonists

THE commoner forms of muscular dystrophy, both in man and in animals, are determined by a single gene change, but the mechanism whereby the complex set of symptoms develops is unknown. Chickens homozygous for muscular dystrophy have been bred, and form probably the closest animal model for the human disease so far investigated[1,2]. Dystrophic line 304 of the Davis (California) flock, for example, has been bred for rapid appearance of the symptoms and shows some signs of muscle weakness at 7–10 d *ex ovo*, whereas a normal line (200) of chickens with closely related genetic background is also available[1,2]. Two of us have reviewed[3] evidence that 5-hydroxytryptamine (5-HT) is involved in some way in the development of the symptoms of muscular dystrophy, and reported that administration of a 5-HT antagonist, methysergide, retards the development of the symptoms in line 304 chickens. We report here that this effect is more general, in that a second anti-serotoninergic drug of entirely different chemical struc-

Fig. 1 Mean FN (○) and plasma CPK level[8] (●) for untreated dystrophic chickens, as a function of age (50–82 animals were used per point). The horizontal line shows the constant FN for the normal chickens from day 10 onwards.
Fig. 2 Percentage of the untreated dystrophic population (50–82 animals per point) giving FN = 0 (●), and the corresponding plasma CPK level (○).

ture, cyproheptadine, is also effective, and that a combination of the two agents is beneficial.

We first established that the development of measureable symptoms in line 304 dystrophic chickens is regular enough for any drug-induced improvement to be reliably detected. A test[1,4,5] of muscle weakness in dystrophic chickens was used in the form of the 'flip number' (FN)—that is, the number of times (0–5 out of 5) a bird can right itself when placed on its back five times in immediate succession. The considerable increase in the creatine phosphokinase (CPK) content of the blood plasma, known to characterise this disease in the chicken[5,6] and in man[7], was used as a second criterion of muscle damage. Using a total population of 150 dystrophic chickens (line 304, Department of Avian Sciences, University of California, Davis) maintained in groups from different hatches over a 2-yr period, these two parameters were followed from hatching for 80 d. Chickens were maintained in constant conditions (temperature 30–33 °C, 12 h light/dark cycle), and the flip test was given in a precisely standardised manner by a naive observer, at 5-d intervals to avoid an exercise component. CPK testing was carried out in a completely blind fashion on coded sera in another laboratory. Newly hatched chicks of the normal line do not develop sufficient muscle strength to give FN=5/5 until 7–10 d of age and show high variability until then, but thereafter are constant, all at 5/5 (Fig. 1). The dystrophic chicks improve partially until about 3 weeks of age, and thereafter show a sharp decline to low scores, eventually zero. The plasma CPK level increases by about 400% throughout the latter period (Fig. 1). We have found that a very good correlation between the muscle weakness and release of CPK from the muscle can be demonstrated (Fig. 2) using as the measure of the former the FN_0 value—that is, the percentage of the dystrophic population that fails totally (having FN=0/5).

With this baseline for comparison, birds injected[3] (twice

daily, intraperitoneally) with cyproheptadine hydrochloride (Periactin, donated by Merck, Sharp and Dohme, Rahway, New Jersey) from day 3 *ex ovo*, were tested. Untreated animals were given water injections similarly throughout. At a low dose regime (for the chicken), substantial improvement in the FN value was shown (Fig. 3). A medium level dose (12 mg kg⁻¹ d⁻¹) extended the later period of this effect, but the performance still declined sharply after day 55. The latter decline was further postponed by a combination of higher doses of cyproheptadine and methysergide (Fig. 3). For the latter case, all the treated animals remained at a passing level (FN=4–5) up to day 60, whereas all of the untreated birds were below this level from about day 30. Similarly, the FN_0 values for animals treated with cypro-

Fig. 3 Mean FN of cyproheptadine-treated or untreated (●), (see Fig. 1) dystrophic chickens. Low dosage regime (△, n = 12) was 2.4 mg kg⁻¹ d⁻¹ at days 3–16, 6.0 at days 17–43 and 8.0 at day 44 onwards. Medium dosage (□, n = 9) was 12.0 mg kg⁻¹ d⁻¹ from day 3 onwards. A combined treatment (○, n = 27) was also given, with cyproheptadine at 8.0 mg kg⁻¹ d⁻¹ at days 3–10, 12 at days 11–30, 17.5 at days 31–52, and 23 at day 53 onwards, plus methysergide at 12.5 mg kg⁻¹ d⁻¹ at days 3–15, 20 at days 10–30, 41 at days 31–45, and 52 at day 45 onwards.

heptadine or with the combination showed a pronounced difference from the untreated dystrophics (Fig. 4).

Using the criterion of CPK release, cyproheptadine-treated animals also showed a smaller change than the untreated birds (Fig. 5). The tendency to stabilise at a plateau of about 2,500 mU CPK per ml plasma in the treated birds, compared with about 8,500 in the untreated birds, is seen more clearly for the treatment with the two drugs combined.

Statistical data for points where divergences were

Table 1 FN differences in treated and untreated chickens

	10–13	Days *ex ovo* 41–44	56–60
Untreated	2.3±0.3 (57)	1.2±0.2 (56)	0.3±0.2 (56)
Methysergide	3.3±0.6 (15) [12.5]	5.0±0.0 (11)* [41]	4.0±0.7 (10)* [51]
Cyproheptadine	3.0±0.4 (9)	4.8±0.2 (9)*	1.7±0.8 (9)**
Methysergide + cyproheptadine		5.0±0.0 (27)*	4.6±0.1 (27)*

Values represent mean FN±s.e.m. for dystrophic chickens, with the number of animals used in parentheses. For the progressive dosages of cyproheptadine (medium dose) and the combination, see Fig. 3; for methysergide the dose level at each period is given in square brackets (in mg kg⁻¹ d⁻¹). Significance (using *t* test) from untreated dystrophic group: *$P < 0.001$; **$P < 0.01$.

Fig. 4 Percentage of the population of dystrophic chickens having FN = 0, when untreated (●, n = 15), or treated with cyproheptadine (○, dose low or medium, see Fig. 3; n = 21) or treated with both drugs (□, doses as stated for Fig. 3; n = 27, or, for last point only, 15).
Fig. 5 Plasma CPK content of dystrophic chickens, untreated (broken line, mean of 18 birds per point), or treated with cyproheptadine (with FN — 5; ●, mean of 8 per point), or with both drugs (with FN = 5; □, mean of 9 per point). O, Normal chickens (mean of 14 per point).

apparent are illustrated in Table 1. Standard errors typical of the CPK determinations have been given elsewhere[3]. For all cases a highly significant difference was found between the untreated and the treated groups, with cyproheptadine over days 30–55, and with the combination of drugs from day 30 to the end of the study.

The two drugs used are already administered chronically in man for other conditions. In the mouse[8] LD$_{50}$ for toxicity of cyproheptadine given intraperitoneally is 55 mg kg^{-1}. In the chicken, it seems to be of still lower toxicity, perhaps denoting a more rapid removal or metabolism, since we have been unable to observe toxic symptoms at higher doses than that. We will report elsewhere more details of the conduct of the therapeutic trials, of histological evidence that parallels the other criteria, and of the lack of any effect in the dystrophic birds of these drug treatments on plasma enzymes unrelated to muscle disease.

There has been a long standing debate on the possibility of a change in blood circulation or of anoxia as a component in dystrophy (see refs 10 and 11). Our results may be attributable to antagonism of a 5-HT-induced effect on the microvasculature of dystrophic muscle, if such a component is indeed significant in inherited dystrophy; but that assumption is not as yet justified since the amelioration could, alternatively, arise by antagonism of an action of 5-HT elsewhere—for example, directly on the muscle[12]. In either case, the results suggest that an investigation in these chickens of a range of 5-HT antagonists could be of therapeutic interest, and they may provide a clue to one of the determinants of the dystrophic process.

M.S.H. thanks the Muscular Dystrophy Association of America for a Postdoctoral Fellowship. We thank Miss C. Pollina for assistance, and Drs D. W. Peterson and B. W. Wilson (Davis) for help with the supply of chickens: the flock used is maintained with the aid of MDAA.

Altered erythrocyte membrane phosphorylation in sickle cell disease

For several years evidence has been accumulating to indicate that the erythrocytes of individuals with sickle cell anaemia not only contain an abnormal haemoglobin but also exhibit several altered membrane characteristics. These include increased cation transport[1], possible alterations in phospholipid arrangement[2], and increased membrane rigidity[3]. The protein and glycoprotein content of membranes from erythrocytes of individuals with sickle cell anaemia does not seem to differ from that of normal erythrocyte membranes[4]. Many of the altered membrane characteristics appear to be a function of altered erythrocyte membrane structure due to membrane–haemoglobin interactions[5], however, whether or not other membranous protein–protein interactions are altered is not well documented.

We have recently reported[6] that human erythrocyte membranes contain, as well as a cyclic AMP-dependent protein kinase, another protein kinase which is capable of using either ATP or GTP as its phosphoryl donor. This enzyme is insensitive to regulation by cyclic nucleotides and catalyses the phosphorylation of membrane polypeptides in the area of bands 2 and 3 (nomenclature of Steck[7]). In this communication we report that the autophosphorylation of sickle-cell (SS) erythrocyte membranes by this enzyme differs from that observed with normal cells.

Blood was obtained from non-hospitalised individuals homozygous for haemoglobin S and from normal individuals through the Hematology Clinic at the University of Illinois

Fig. 1 Autophosphorylation of normal (a) and sickle cell (b) erythrocyte membranes in the presence of γ-[32P]P-GTP. Normal (38 µg) and sickle-cell (34 µg) erythrocyte membranes were incubated for 30 min at 37 °C in the presence of 0.1 M glycine-NaOH (pH 8.5), 10 mM MgCl$_2$, 0.2 mM γ-[32P]P-GTP (280 c.p.m. pmol^{-1}). The phosphopeptides were separated by electrophoresis in a 5% polyacrylamide slab gel (containing 0.2% SDS. The figure represents a densitometric tracing of an autoradiogram which was obtained after a 3-d exposure to the dried gel. Other experimental details were as previously described[6].
Phosphoryl donor		2–2.1	3	4.1	4.5–4.8
Table 1 Phosphorylation of normal and sickle-cell erythrocyte membrane polypeptides					
ATP	Normal (5)	1.01±0.05	1.43±0.11	0.05±0.01	0.12±0.02
	SS (5)	0.74±0.05*	1.51±0.13	0.12±0.03	0.24±0.02
ATP (+ cyclic AMP)	Normal (5)	1.27±0.11	1.61±0.13	0.16±0.02	0.43±0.05
	SS (4)	0.94±0.07	1.48±0.23	0.22±0.06	0.58±0.13
GTP	Normal (7)	0.64±0.05	0.57±0.13	0.01±0.01	0.01±0.01
	SS (8)	0.51±0.03†	0.83±0.12	0.07±0.04	0.20±0.03‡

Membranes were phosphorylated exactly as described in Fig. 1 except that γ-^{32}P-ATP (0.2 mM, 250 c.p.m. pmol[-1]) and cyclic AMP (2 μM) were present as indicated. When ATP was used as the phosphoryl donor, the incubation period was 5 min at 37 °C and the auto-radiogram was exposed for 4 d. The values were obtained by integrating the areas under the indicated peaks of densitometric tracings and are expressed as arbitrary densitometric units per μg membrane protein. All values are given as means ±s.e.m. The numbers in parentheses refer to the number of determinations. Statistical determinations were performed using the Student's t test.
* Significantly different from normal, $P < 0.01$.
† Significantly different from normal, $P < 0.05$.
‡ Significantly different from normal, $P < 0.001$.

Hospital. Haemoglobin-free erythrocyte membranes were prepared according to Dodge et al.[1] and stored in liquid nitrogen before use. Membranes were phosphorylated and applied to 5% polyacrylamide slab gels containing 0.2% SDS as previously described[2]. Autoradiograms which were prepared from the dried gels were scanned using a Zeineh Soft-Laser densitometer.

In confirmation of a previous study by others[4], we saw no large differences in the protein content of normal and SS erythrocyte membranes as analysed by SDS–polyacrylamide gel electrophoresis. When we studied the phosphorylation profile of the two types of membranes, however, we saw marked differences when γ-^{32}P-GTP was used as the phosphoryl donor (Fig. 1 and Table 1). As mentioned above, only one of the membrane-bound kinases can utilise GTP as its phosphoryl donor. As seen in Fig. 1 and Table 1, one or more polypeptides which migrate in the area designated as 4.5–4.8 are substrates for the GTP-utilising kinases in sickle-cell but not in normal erythrocyte membranes. This difference is not observed when ATP is used as the phosphoryl donor, either in the presence or absence of cyclic AMP (Table 1).

A second, albeit less marked, difference in sickle-cell membrane phosphorylation is that the phosphorylation of polypeptides 2–2.1 is slightly lower in sickle-cell membranes than in normal erythrocytes when either ATP (in the absence of cyclic AMP) or GTP is used as the phosphoryl donor. Although there is a tendency for the phosphorylation of 2–2.1 in the presence of ATP and cyclic AMP to be less in the SS than in the normal erythrocyte membranes, the data are not significantly different. In the presence of cyclic AMP no significant differences in the phosphorylation of normal and SS membranes are observed.

There are several possible explanations for the observed results. We favour the hypothesis that the conformation of kinase substrates may be altered in the SS membranes. It is conceivable that phosphoryl acceptor sites are covered (as for 2–2.1) or uncovered (as for 4.5–4.8) as a result of repeated sickling and unsickling during the lifespan of the erythrocytes. Alternately, the kinase itself may be altered such that its substrate specificity is decreased. Since the cyclic AMP-dependent protein kinases do not use GTP as a phosphoryl donor[6], it is unlikely that the phosphorylation of 4.5–4.8 in SS erythrocyte membranes in the presence of GTP is attributable to the cyclic AMP-dependent kinase. Further characterisation of the kinetics of the phosphorylation reactions in normal and SS membranes and the solubilisation of the kinases and their substrates is necessary to determine if one or more of these or other factors are responsible for the observed phenomenon.

It is well documented that several aspects of cation content and transport are altered in SS erythrocytes[1]. In addition, there are several lines of evidence implicating membrane phosphorylation in the regulation of cation

transport[10],[11]. Whether or not the altered membrane phosphorylation of SS erythrocytes plays a role in the altered transport processes in these cells or in other membrane phenomena remains to be determined.

We thank Dr E. Popescu for the sickle cells. This work was supported by the American Cancer Society. M. Hosey is the recipient of a National Institutes of Health Fellowship. M. Tao is an Established Investigator of the American Heart Association.

Inhibition of intercellular adhesion in a cellular slime mould by univalent antibody against a cell-surface lectin

THE cellular slime moulds, *Dictyostelium discoideum* and *Polysphondylium pallidum* contain carbohydrate-binding proteins (lectins) that increase significantly in amount in soluble crude extracts as amoebae differentiate from the vegetative stage (when the cells do not associate) to the aggregation-competent stage (when the cells can form stable intercellular contacts)[1-3]. Lectins from the two species, assayed as agglutinins of erythrocytes, have been purified by affinity techniques and, on the basis of their carbohydrate-binding specificities, as well as several physicochemical properties, have been shown to be distinct proteins[3-5]. Distinct lectin activities have also been identified in four other species of slime moulds[6]. The lectins from *D. discoideum* and *P. pallidum* accumulate on the cell surface with development of aggregation competence as demonstrated by erythrocyte-rosette experiments[1,2,7], immunofluorescent and immunoferritin techniques[7,8], and lactoperoxidase-catalysed iodination of intact cells[8]. Both species also contain cell-
Fig. 1 Kinetics of agglutination of aggregation-competent ameobae (●) and vegetative amoebae (○). Vegetative amoebae and aggregation-competent amoebae were collected after 55 h and 96 h of incubation on agar, respectively. Cells were washed several times in cold water to separate them from bacteria and were then suspended at 9×10^6 ml^{-1} in EDTA–phosphate buffer (16.7 mM Na$_2$HPO$_4$–KH$_2$PO$_4$, 10 mM EDTA, pH 6.2) containing 0.2 M D-glucose and 1 mg ml^{-1} bovine serum albumin (BSA). The cell suspension was dispersed into single cells by repeated Manostat pipetting. After 30 min in an ice bath, the cell suspension was again dispersed as above. A 500-μl sample of the cell suspension was added to each of several individually cut out wells of a Linbro plate (16 mm diameter, FB–54). The wells were gyrated at 115 r.p.m. on a New Brunswick G-24 shaker (radius of gyration 3/4 inch) at 22 °C. At various times, the contents of wells were carefully poured into plastic vials containing 20 ml of EDTA–phosphate buffer. The vials were gently mixed and after 5 min, to allow osmotic re-equilibration, single cells were counted with a Coulter Counter (Model ZBI, 100-μm aperture, 1/amplitude = 1, 1/aperture current = 0.354, impedance = 10 K, threshold = 10–60). With these settings, approximately 90% of the single cells were counted. The total number of cells present in the suspension was determined by dispersing the agglutinates into single cells by Manostat pipetting and counting at the above settings. The percentage agglutination was computed as the percentage of single cells that entered into aggregates. Two wells were used for each time point. Readings on independent samples agreed to within 5%.

surface receptors with a very high affinity for the homotypic lectin and a lesser affinity for the heterotypic lectin[10], suggesting a possible basis for species-specific intercellular affinities. In the case of *D. discoideum*, we have shown that the high affinity receptor appears on the cell surface as amoebae differentiate into the cohesive state[10].

This series of findings raises the possibility that intercellular adhesion in the cellular slime moulds is mediated by the association of cell-surface lectins with complementary surface receptors, presumed to contain complex oligosaccharides. This possibility is supported by the finding that cohesiveness of aggregation-competent *P. pallidum* cells is inhibited by specific simple sugars that react with pallidin, the lectin derived from this species[2]. High concentrations of these sugars are, however, required (0.1 M or higher), suggesting the possibility of nonspecific effects on unknown components of the cell, rather than inhibition of cell-surface pallidin. To test the possibility that pallidin on the surface of *P. pallidum* amoebae is indeed involved in the developmentally regulated cohesiveness of these cells, we raised antiserum to purified pallidin and determined the effect of Fab fragments, derived from the antibodies, on the cohesiveness of *P. pallidum* cells. We now report that these univalent antibodies inhibit the cohesiveness of differentiated amoebae.

Polysphondylium pallidum strain WS 320 was grown in the dark in the presence of *Aerobacter aerogenes* on

nutrient agar at 22 °C with 10^5 spores inoculated on each 100-mm agar plate, as described previously[2]. In these conditions, the amoebae became aggregation competent by 96 h when the bacteria had been substantially cleared. The absence of light prevents the cells from aggregating and proceeding through culmination. On illumination, however, aggregation of the cells is apparent within 30 min. Vegetative cells were obtained after 55 h of culturing, when a thick carpet of bacteria still covered the agar. These cells, once free of bacteria, require a several-hour interphase period before they are aggregation competent. Cells of both stages were collected and washed as previously described[2]. An index of cell cohesiveness was obtained by gyrating a suspension of mechanically dispersed cells and determining the percentage reduction in single cells as they agglutinated. In the hypertonic assay conditions used (see Fig. 1), only the aggregation-competent cells formed agglutinates, whereas vegetative amoebae remained as single cells. The critical factors in this assay, including a morphological study of the agglutinates by transmission and scanning electron microscopy, will be presented later.

Pallidin was purified by affinity adsorption[5]. The purified protein gave a single band on polyacrylamide electrophoresis in the presence of sodium dodecyl sulphate and 2-mercaptoethanol, even when as much as 200 μg of protein was applied to the gel. Antiserum, raised in a rabbit using a conventional procedure as described previously[7], formed a single precipitin band on immunodiffusion against either
Fig. 2 Effects of immune (●) and normal Fab (○) on *P. pallidum* agglutination. Cells were collected after 96 h of incubation, washed and suspended to 1.8×10^7 ml^{-1} in EDTA–phosphate buffer containing 0.4 M D-glucose and 2 mg ml^{-1} BSA. Aliquots of the cells were dispersed and mixed with equal volumes of varying concentrations of normal or immune Fab diluted in EDTA–phosphate buffer. After a preincubation period of 30 min at 0 °C, the cells were dispersed again and added to Linbro plastic wells, 500 μl per well. After 30 min of gyration by which time equilibrium was approached, the percentage of cells that entered into agglutinates was determined as above (see Fig. 1 legend). For each of a series of concentrations of normal and immune Fab, the percentage of the control level of agglutination in the absence of Fab was computed. Two replicate wells were used per treatment. Protein concentration was determined by the Lowry method using BSA as a standard.

purified pallidin or crude extracts of *P. pallidum* cells. IgG was purified by ammonium sulphate precipitation followed by DEAE–cellulose chromatography[11]. Fab fragments were derived by papain digestion and purified by the standard procedure[12]. Control Fab fragments were prepared in parallel from normal rabbit serum.

The Fab fractions were assayed for their ability to inhibit haemagglutination produced by purified pallidin in a standard assay. The reaction mixture added to the wells of a Microtier V plate was as follows: 25 μl of a twofold dilution series of pallidin in 75 mM NaCl, 75 mM Na_2HPO_4–KH_2PO_4, (pH 7.2 PBS), 25 μl of formalinised human O erythrocytes[2] 2.5% (v/v) in PBS; and 25 μl of Fab diluted in 16.7 mM Na_2HPO_4–KH_2PO_4, 10 mM EDTA (pH 6.2). At a final concentration of 0.5 μg ml^{-1}, immune Fab reduced the haemagglutination titre by 50%: normal Fab did not produce inhibition at concentrations up to 250 μg ml^{-1}.

Immune Fab (at 3 μg ml^{-1}) directed against pallidin inhibited the cohesiveness of *P. pallidum* cells by 50%, whereas control Fab had little effect (Fig. 2). Inhibition of agglutination was also obvious on microscopic inspection.

Beug and colleagues[13,14] have demonstrated that Fab fragments from antisera against crude fractions of differentiated *D. discoideum* amoebae block cohesion of *D. discoideum* cells; but in this case the cell-surface antigens with which the contact-blocking Fab fragments react are not known. In the present experiments, Fab fragments directed against the cell-surface lectin, pallidin, were shown to inhibit cohesiveness of differentiated *P. pallidum* cells, as measured in a gyrated suspension. Although further experiments are required to fully define the morphogenetic role of the cellular interactions measured by our cohesiveness assay, we assume that this experimentally defined cohesiveness is functionally significant, since it is correlated with the ability of cells at different developmental steps to form stable intercellular contacts when moving on a solid substratum. Together with other evidence summarised here and reviewed elsewhere[15], the present experiments provide strong support that stage-specific intercellular adhesion is mediated by the cell-surface lectin, pallidin.

New approach to determination of specific functions of platelet membrane sites

IT has been suggested that the layer of bound carbohydrate on the surface of a platelet contains groupings vital to the haemostatic function of the platelet[1]. This haemostatic role is largely dependent on the ability of the platelet to adhere to exposed subendothelial components in the event of vessel damage[2]. Platelet aggregation, induced by bovine factor VIII and ristocetin, and platelet adhesion to subendothelium are impaired in the Bernard–Soulier syndrome, while aggregation induced by ADP is apparently normal[3,4]. A gross abnormality in the 155,000-molecular weight glycoprotein seen in membrane fractions prepared from platelets from this syndrome[5] suggests that the glycoprotein acts as an acceptor–receptor during the interation with subendothelium and macromolecular aggregation-inducing agents. Here we report further evidence that a specific site on the platelet is required for ristocetin and bovine factor VIII to induce platelet aggregation and for platelet adhesion when aggregation and platelet adhesion to subendothelium are inhibited by an acquired antiplatelet antibody found in a polytransfused Bernard–Soulier patient. This antibody induced *in vitro*, on normal human platelets, a specific Bernard–Soulier-like defect, so that adhesion to subendothelium was impaired and aggregation with ristocetin and bovine factor VIII was defective, while ADP-mediated aggregation was unaffected.

The antibody, which was shown to be an IgG, was isolated from the plasma of a Bernard–Soulier patient (P) who had received multiple transfusions of platelet concentrates during the arrest of a bleeding episode. It seemed to differ from the usual antiplatelet alloantibodies: a negative complement fixation test was observed with a panel of 25 control human

Fig. 1 Effect of different dilutions of the antibody from patient P on the aggregation of control human PRP induced by ADP, collagen, bovine factor VIII and ristocetin. Citrated control human PRP (0.2 ml) was incubated for 60 s in the cuvette of a Born MK II miniaggregometer (produced by the Department of Pharmacology, Royal College of Surgeons, London) in the presence of several different non-agglutinating dilutions of the antibody (in saline) before addition of 10 μl of one of the following inducers (final concentration): ▲, 0.6 μmol of ADP (Sigma); ×, 20 μg of collagen (Stago, Asnières); □, 160 μg of bovine factor VIII (AB Kabi, Stockholm); ○, 200 μg of ristocetin (Lundbeck, Copenhagen). Results (mean values) of 10 experiments are expressed as the percentage inhibition of the aggregation intensity in the absence of antibody.

Final dilutions of antibody

Table 1 Consumption studies of the antibody from patient by platelet stroma

Antibody final dilution	Residual agglutinating activity with control PRP after incubation with				Residual inhibitory effect on ristocetin-induced aggregation of control PRP after incubation with			
	Saline	Control platelet stroma	B S 1 platelet stroma	B S 2 platelet stroma	Saline	Control platelet stroma	B S 1 platelet stroma	B S 2 platelet stroma
1:20	50	12	60	55				
1:40	15	0	18	16	80	10	45	50
1:80					45	5	20	45

Hypercitrated PRP from control human or two other Bernard-Soulier patients, BS1 and BS2, were centrifuged for 10 min at 2,000g and 15 °C. Platelets pellets were resuspended in 0.015 M Tris-HCl buffer, pH 7.4, containing 0.135 M NaCl, 0.053 M KCl and 0.015 M EDTA. These pellets washed twice in this buffer, then finally resuspended in the same buffer without EDTA, were disrupted by five times freeze–thawing and washed twice in saline (27,500g, 15 min, 15 °C) to remove most of the intracellular constituents. The stromas were resuspended at a concentration of 1 mg of protein per ml in saline. Samples (0.2 ml) of this membrane-enriched fraction or 0.2 ml of saline were incubated with 0.2 ml of different dilutions of 6 mg of the antibody solution (final dilutions of the antibody were 1:20, 1:40, 1:80) for 120 min at 37 °C, followed by overnight incubation at 4 °C. After centrifugation at 27,500g for 15 min at 15 °C, the supernatants were tested for their residual agglutinating activity (left hand side) on control PRP (results expressed as percentage of agglutination) and inhibitory effect on ristocetin-induced aggregation (right hand side) of control PRP (results expressed as percentage of inhibition of the intensity of ristocetin aggregation). Mean values of three experiments.

platelets by a microtechnique described before[6], the lymphocytotoxicity test of Terasaki and McClelland[7] revealed only a weak anti-HLA-A1 antibody, and the thromboagglutination test[8] was positive on 20 control human platelets whatever the HLA, PLA$_1$, KOa or KOb type. When control citrated platelet-rich plasma (PRP) from 50 donors was incubated at 37 °C and stirred in a Born MK II miniaggregometer cuvette in the presence of the antibody, agglutination was observed after about 1 min. The intensity of the agglutination of control PRP was directly related to the concentration of antibody added. No agglutination was observed with a final dilution greater than 1:40. PRP from a patient with severe quantitative von Willebrand disease was normally agglutinated by the antibody. In contrast no agglutination effect (at any dilution) was observed when the antibody was added to PRP obtained from two other Bernard–Soulier patients. Using PRP from the family of one of these patients, we found that the agglutinating effect of the antibody from patient P was nil for an apparently healthy brother, about 60% of normal for another healthy brother and also for the mother and the father, making possible a distinction between the normal and heterozygous state.

Figure 1 shows that the antibody from patient P was a strong inhibitor of aggregation induced by ristocetin and bovine factor VIII. The inhibitory effect was related to the concentration of antibody used. In contrast, ADP or collagen-induced aggregation were not inhibited by the antibody. Table 1 shows that after incubation with control platelet stroma, both agglutinating activity and inhibition of ristocetin-induced aggregation by the antibody were suppressed, while with the platelet stroma of the two other Bernard–Soulier patients,

Table 2 Effect of antibody from patient P on interaction of platelets with rabbit aorta subendothelium

Antibody final dilution	Interaction of platelets with aorta subendothelium	
	Naked	Adhesion
0	28±12	72±12
1:80	43	57
1:40	76	24

The procedure was as described by Baumgartner[2]. Everted segments of rabbit aorta, previously denuded of endothelium were mounted on the central rod of a perfusion chamber. Citrated whole blood from donors was first incubated for 10 min with the antibody (final dilutions 1:40, 1:80) or with saline before being circulated for 10 min at 37 °C with an average flow rate of 160 ml min^{-1} through the chamber. After the chamber had been rinsed with phosphate buffer, the blood vessel segments were fixed and embedded in Epon for examination by light microscopy and for evaluation of platelet interaction with subendothelium. Results are expressed as the percentage of the subendothelial surface that is devoid of platelets (naked) or that is covered by adherent platelets (adhesion). Results of control without antibody are given as the mean values of 10 experiments±1 s.d.

much of the antibody activity was recovered in the supernatant. In the presence of antibody dilutions that inhibited 100% of control PRP ristocetin-induced platelet aggregation, platelet adhesion to subendothelium was estimated by the Baumgartner technique[2] to be 24% compared with 72% without antibody (Table 2).

The agglutinating effect of the antibody from patient P on control human PRP and not on the two other Bernard–Soulier PRP, could indicate that the antibody was an antiplatelet antibody directed against an antigen present on all normal platelets but absent, very reduced or abnormal on Bernard–Soulier platelets. This suggestion is supported by the fact that control human platelet stromas consumed the antibody while Bernard–Soulier platelets were much less efficient in doing so. Using subagglutinating dilutions of the antibody from patient P, we have demonstrated the strong and specific inhibition of aggregation induced by ristocetin and bovine factor VIII while ADP and collagen aggregation were not influenced. In the presence of the antibody, adhesion of normal platelets to subendothelium was much reduced; this may indicate that the antigen recognised by the antibody was necessary for the aggregation inducing agents bovine factor VIII and ristocetin, and for adhesion to subendothelium, but not for aggregation mediated by ADP and collagen. The antibody was not directed against von Willebrand factor, for it induced normal agglutination of PRP from severe quantitative von Willebrand disease. Furthermore, von Willebrand factor activity in ristocetin-induced platelet aggregation was normal in the fraction eluted in the void volume after gel filtration on Sepharose 2B of plasma from patient P[3].

As the platelets of patient P had a surface defect involving a membrane glycoprotein[4], we suggest that the antibody is directed against a specific platelet site, implicated in the interaction with subendothelium and macromolecular aggregation-inducing agents. This antibody makes possible a distinction between the surface groupings involved in aggregation induced by ADP and collagen on the one hand, and in aggregation induced by ristocetin and bovine factor VIII and adhesion to subendothelium on the other hand. The platelet antigen recognised by the antibody could be the 155,000 molecular weight glycoprotein, but the exact antigenic site of the molecule remains unknown and is under investigation.

Kinetics of agonist-induced intrinsic fluorescence changes in membrane-bound acetylcholine receptor

ACETYLCHOLINE receptor(AChR)-rich membranes derived from fish (*Electrophorus* and *Torpedo*) electric organs have been used extensively for *in vitro* binding and functional studies[1]. These membrane fragments (microsacs) are particularly suited for physical investigations of AChR–ligand interactions because of their inherently high content of receptor, retained in its natural environment. A number of extrinsic fluorescent probes have been applied to the determination of binding specificity, equilibria and, in a preliminary way, kinetics at the level of the isolated membrane, as well as the neuromuscular junction and purified receptor[1–4]. We report here the existence of intrinsic protein fluorescence changes, induced in membrane fragments from *Torpedo marmorata* electroplaques by the natural neurotransmitter acetylcholine. We have used highly sensitive fluorescence kinetic techniques to obtain the concentration dependence and some of the corresponding equilibrium and
rate constants for the initial binding and subsequent isomerisation reactions. The latter can be correlated with electrophysiological data and the functional properties of the post-synaptic membrane[7–9], particularly with respect to the process of desensitisation, and with other quantitative results obtained with the same microsac preparations[10]. In particular, our data provide physical evidence for the existence of at least three conformational states of the cholinergic receptor protein *in situ*, interrelated by reversible kinetic processes.

AChR-rich microsacs were prepared essentially as described by Cohen *et al.*[11], and their α-toxin-binding capacity determined by the Millipore filter assay[1a]. Fluorescence kinetic experiments were carried out in the stopped-flow apparatus designed in this laboratory[1a]. Further experimental details are given in the legends to Figs 1 and 2.

Figure 1 shows the changes in the intrinsic fluorescence of the membrane-bound AChR induced by mixing with the natural neurotransmitter, ACh, and another cholinergic agonist, carbamylcholine. An exponential decay in fluorescence was observed on the addition of more than 10 μM ACh to the microsacs (Fig. 1a). This initial response reversed to the original fluorescence decay after a delay which increased with increasing ACh concentrations or with a decreasing acetylcholinesterase (AChE) content of the microsacs. The decay, and its reversal, were superimposed on a uniform linear decrease in fluorescence emission probably due to photolysis caused by the high illumination intensities in the stopped-flow apparatus. (The drift could be determined easily and corresponded to a -0.012% s^{-1} relative change in fluorescence—that is, much slower than the ligand-induced effect. All records were corrected appropriately.)

At ACh concentrations < 2 μM, the initial response was no longer monoexponential and its magnitude was markedly reduced, presumably due to rapid degradation of the ligand by the AChE present in the partially purified microsacs. In the presence of small amounts of the AChE inhibitor paraoxon

(diethyl-*p*-nitrophenylphosphate, 150 nM), however, the ACh-induced fluorescence quenching could be followed over a wide concentration range (Figs 1*b* and 2).

The relaxation times and amplitudes characterising the progress curves after mixing were concentration dependent but reached plateau values at high ACh levels (Fig. 2). Over a limited concentration range, an additional faster exponential decay in fluorescence was seen (Figs 1*c* and 2) but was not detectable elsewhere, for reasons given below.

Similar kinetic phenomena, except for the reversal were observed with another agonist, carbamylcholine, which is not hydrolysed by the esterase (Fig. 1*d*). The relaxation time and amplitude, however, reached constant values at significantly higher concentrations of carbamylcholine as compared with ACh (65 against 4 μM, respectively).

The specificity of the ligand-induced fluorescence changes and their attribution to distinct states of the receptor protein follow from findings that: the effects were abolished by pre-incubation with a tenfold molar excess of α-cobrotoxin; and the total amplitude of the fluorescence quenching was proportional to the specific activity (in terms of toxin binding) of various microsac preparations and not to the total protein or AChE content. The essential reversibility of the phenomenon—that is, the return of the AChR to its initial resting state—is attested to by the reversal observed as a consequence of dissociation and enzymatic hydrolysis of the free transmitter. The onset time and time course of the reversal were in good agreement with expectation on the basis of AChE determinations using acetylthiocholine[14].

The simplest reaction mechanism consistent with our experimental results consists of a fast binding step followed by a slow isomerisation

$$A + R \underset{k_2}{\overset{k_1}{\rightleftharpoons}} AR \underset{k_4}{\overset{k_3}{\rightleftharpoons}} AD \qquad (1)$$
where A is the agonist and R and D are two distinct conformers of the AChR. The experimentally observed slow relaxation time, τ_{II}, corresponds in this sequential scheme to the equilibration of the second step to which the first is thermodynamically coupled

$$(\tau_{II})^{-1} = \left[\frac{A}{K_1 + A}\right] k_3 + k_4 \qquad (2)$$

where K_1 is the dissociation constant (k_2/k_1). The reciprocal relaxation (Fig. 2) has an ordinate intercept of k_4, an initial slope of k_3/K_1 and a limiting value at high [A] of $k_3 + k_4$. The corresponding amplitude (in terms of relative fluorescence) is given by

$$\alpha_{II} = \alpha_{total} - \alpha_I = \left[\frac{A}{K_1 + A(1 + K_2)}\right](\Delta\Phi_1 + K_2\Delta\Phi_2)$$
$$- \left[\frac{A}{K_1 + A}\right]\Delta\Phi_1 \qquad (3)$$

where $\Delta\Phi_1$ and $\Delta\Phi_2$ are the fractional changes in fluorescence on passing from state R to states AR and AD, respectively, and K_2 is the isomerisation equilibrium constant (k_3/k_4). α_{II} has an ordinate intercept of zero, an initial slope of $K_2\Delta\Phi_2/K_1$, a maximum magnitude at $[A] \sim K_1(K_2\Delta\Phi_1/\Delta\Phi_2)^{-\frac{1}{2}}$ and a plateau value of $K_2(\Delta\Phi_2 - \Delta\Phi_1)/(1 + K_2)$.

Using the above formulation, it was possible to fit the data obtained at various concentrations of ACh or carbamylcholine with one set of parameters for each agonist (Fig. 2 and Table 1). It is seen that carbamylcholine has a lower affinity for the R state of the receptor but the transition from the AR to the AD state is more rapid and extensive (k_3 and K_2 larger than for

ACh). The fluorescence parameters, however, are about the same for both drugs, and indicate that the emission of the receptor in the states R, AR, and AD decreases in that order. The values of K_1 for both ACh and carbamylcholine agree well with the apparent dissociation constants derived from [²²Na] efflux measurements in the microsac preparation and from direct binding to solubilised receptor[10].

The limited data for the rapid decay process (Figs 1 and 2) do not suffice for the determination of the corresponding rate constants, although k_1 is certainly $> 10^6$ M^{-1} s^{-1}. Thus, at low ACh concentration (for example, 1 μM), α_I is too small ($\leqslant 0.2\%$), whereas at high concentrations (> 40 μM), τ_I is too small (< 10 ms) for the relaxation to be perceptible directly. Its presence is indicated nevertheless by the decrease in α_{II} at high levels of ACh (Fig. 2).

The addition of a further rapid isomerisation step between an inactive complex AR (equation 1) and a conducting form AR′ does not alter the ability of the above formulation to account for the data of Fig. 2 (except to change the quantitative interpretation of K_1 and k_3). Such a scheme is required to rationalise the submillisecond rise time of the endplate potential[8,15] and the analyses made of potential fluctuations (membrane noise)[16,17]. If the AR–AR′ equilibrium is rapidly established and particularly if it favours the AR state[17], we would fail to detect it due to the 3–5 ms time resolution of the conventional stopped-flow apparatus[31], even if a distinct fluorescence change were involved.

The second relaxation process is most likely related to the formation of an inactive or 'desensitised' state of the receptor (AD), a phenomenon which occurs in *T. marmorata in vivo*[18] and *in vitro*[10,19,20] and, moreover, generally in the cholinergic synapse[8,9,21–24]. The rate constant k_3 (Table 1) indicates that desensitisation occurs in the time range of seconds, a finding compatible with most electrophysiological data. In addition, other studies (unpublished results) have shown the expected influence of temperature and of effectors known to influence desensitisation on the fluorescence relaxation process. Although the simple scheme outlined above accounts well for the experimental results, the rapid reversal of the fluorescence decay on ACh hydrolysis (Fig. 1*a*) suggests the existence of an alternative route for recovery from the desensitised state with a rate > 0.1 s^{-1} (and thus incompatible with the value of k_4, Table 1). This phenomenon, which may to a limited degree represent the physiological situation, is consistent with a cyclic scheme

Fig. 2 Dependence on ACh concentration of the fluorescence decay rates (τ^{-1}) and amplitudes (α) after mixing AChR-rich microsacs with ACh in the stopped-flow fluorimeter. Specific activity: 1,000 pmol α-toxin-binding sites per mg protein. AChR concentration after mixing was 20 nM in α-toxin sites. ■, Decay rate measured in the presence of the AChE inhibitor paraoxon (300 nM); □, decay rate measured in the absence of the AChE inhibitor; ●, observed amplitude of decay in fluorescence in the presence of 300 nM paraoxon; ○, amplitude measured in the absence of paraoxon; ▲, amplitude of fast decay in fluorescence observed at 4 μM ($\tau_I = 120$ ms) and at 12 μM ($\tau_I = 32$ ms) ACh, with the same membrane preparation used in experiment shown in Fig. 1*c*. Solid lines correspond to the theoretical curves calculated for the sequential scheme (equations (1) and (2)) using the values given in Table 1.

$\Delta\Phi_2$	−1.7%	−1.5%

*In the presence of 150 nM AChE inhibitor, paraoxon. Temperature: 20 °C.

†From Table 2 in ref. 10.

‡This and related values have been normalised to a specific activity of 1 nmol ^{3}H-α-toxin per mg protein. The measured fractional fluorescence changes, $\Delta\Phi_1$ and $\Delta\Phi_2$, are related to the actual relative changes in the fluorescence of the AChR by a proportionality factor β which denotes the fractional contribution made by the receptor to the total protein emission. That is, the true changes associated with the intrinsic AChR fluorescence are given by $\beta\Delta\Phi_1$ and $\beta\Delta\Phi_2$, where β could have a value ≥ 10.

extending equation (1) to include the dissociation of the AD complex and the isomeric transition of the D to the R state. Such a mechanism, which was considered originally by Katz and Thesleff[21] and developed further by Rang and Ritter[22,23] best fits available pharmacological data[8,9]. Our results indicate that the desensitised receptor has a much higher affinity for the agonist than does the resting state ($K_3 < K_1/K_2 \ll K_1$, where K_3, the dissociation constant for the AD state, must be < 0.3 µM to account for the consistency of the data with the sequential scheme).

It is important to note that regardless of the true binding order associated with activation (that is, number of ligand molecules required per functional receptor, a value which may well exceed one[7–9,25–27]) the isomerisation step (desensitisation) we have observed seems to proceed from a mono-liganded state (we cannot exclude the presence of other more tightly bound ligand molecules). This finding suggests that if binding of additional molecules is required for activation, it involves only a small proportion of the available receptors.

Conformational changes in the cholinergic receptor have been invoked to explain drug antagonism (the 'metaphilic effect'[28]), agonist efficacy[29,23,7], agonist-dependent mean channel conductance[30], and numerous *in vitro* observations, including those derived using fluorescence probes[1,3,6]. The advantages of using intrinsic protein fluorescence in such studies are twofold: there is a minimal perturbation of the system; and natural ligands can be used at high concentration without loss of specificity or sensitivity. The magnitudes of the effects we have observed, though small, seem to be specific. Studies now in progress are aimed at characterising the structural changes responsible for the fluorescence states of the AChR.

We thank Drs P. Adams and R. Clegg for valuable comments and Mrs A. Zechel for assistance.

Virtual absence of L-glutamate from the haemoplasm of arthropod blood

DURING the past decade substantial evidence has accumulated that L-glutamate is a transmitter at arthropod somatic neuromuscular junctions[1]. One of the major paradoxes in the acceptance of this evidence is the reported high concentration of L-glutamate in the haemolymph, which is sufficient on neurophysiological preparations to decrease or abolish neurally-evoked contractions[2,3]. To overcome this problem it has been suggested that either there is a barrier to L-glutamate between the neuromuscular junction and the haemolymph[3,4], or L-glutamate is bound in the haemoplasm in a pharmacologically inactive form[5] or sequestered into the haemocytes[6,7]. These suggestions would now seem to be obsolete in view of our evidence that L-glutamate is virtually absent from arthropod haemoplasm.

The neuromuscular junctions of *Lucilia sericata*, in common with other blowfly larvae, are not covered by glial cells[8,9] and so there is no cellular barrier between the synapse and the L-glutamate in the haemolymph. Injection of L-glutamate into the haemolymph of larval *L. sericata*, as found with larval *Calliphora vicina*[6], caused reversible paralysis, confirming that there is no apparent barrier to L-glutamate between the haemolymph and the neuromuscular junction in this *in vivo* preparation. Furthermore, injection of radiolabelled L-glutamate into the haemolymph reveals rapid metabolism and removal of L-glutamate to other tissues, which indicates that the L-glutamate is not bound in the haemoplasm in a pharmacologically inactive form. As fresh haemolymph has been reported to be pharmacologically inactive[5], an investigation into the electrophysiological effects of fresh haemolymph on body wall muscles 6A and 7A of *L. sericata*[10] was undertaken. These muscles are sensitive to L-glutamate which causes muscle membrane depolarisation and contraction. The effect on the membrane potential when fresh haemolymph was applied was unpredictable individually, but when repeated many times gave no significant difference between the membrane potentials before and after haemolymph application ($n = 105$). Aged haemolymph gains pharmacological activity in *Schistocerca gregaria*[6] and this is also true for aged *L. sericata* haemolymph, which evokes physiological responses similar to those elicited by L-glutamate.

Fresh haemolymph is thus pharmacologically inactive, and no barriers (physical or chemical) seem to exist between the neuromuscular junction and the haemolymph. One possible conclusion is that the haemoplasm does not contain L-glutamate and so to test this hypothesis, we analysed the haemolymph of various insects using a Locarte automatic amino acid analyser (Table 1 and Fig. 1). The haemolymph from individuals of each species was pooled, to give samples of 30 µl which were centrifuged for 4 min at 800g, the haemoplasm removed and the proteins precipitated using mainly 70% ethanol, and occasionally

3% sulphosalicylic acid (glutamate recovery 97–99% and 95–98% respectively). The precipitate was removed by centrifugation, resuspended in distilled water, recentrifuged and the supernatants pooled. All experimental procedures were carried out at 4 °C. The results revealed that although there is L-glutamate in the haemocytes of all the species tested, it is not detectable, or only present in trace amounts ($< 10^{-5}$ M) in the haemoplasm. These results have been confirmed qualitatively by high voltage paper electrophoresis (HVPE), and a Beckman 120C amino acid analyser with an initial buffer of pH 3.25, which achieves a discrete glutamate peak away from the glutamine peak. Our data thus clearly contradict the reports of others[2-7,12-14] who found levels of L-glutamate as high as

Fig. 1 Traces taken from Locarte automatic amino acid analyser. 5.8×10^{-4} M (ref. 5) in arthropod haemoplasm. To resolve this contradiction, we studied the methods used by these other workers, and found that these methods are capricious, for the following reasons.

(1) L-glutamine is often the most abundant amino acid in the haemoplasm (10^{-2}–10^{-3} M) and is known to be unstable[15-18] at extremes of pH. Using HVPE and radiolabelled L-glutamine, we found that the common acid protein precipitants (perchloric acid, trichloroacetic acid and sulphosalicylic acid) at the quoted concentrations are sufficient to convert some L-glutamine to L-glutamate and pyrrolidone carboxylic acid (Table 2). Furthermore, perchloric acid left at room remperature in a clear glass vessel shows a dramatic increase in hydrolysing ability (Table 2).

(2) Many published haemolymph extractions were conducted at room temperature[3,5,13]. We found it difficult to prevent the first stages of clotting at room temperature and even at 4 °C half the samples of some species had to be discarded after centrifuging because some clotting had occurred. Haemolymph analysis of these partially clotted samples revealed L-glutamate in the haemoplasm at concentrations as high as 4.5×10^{-4} M. Thus attempts to analyse partially clotted samples of haemolymph of those insects tested will reveal L-glutamate in the haemoplasm. This could explain why aged haemolymph gains pharmacological activity.

(3) Many authors did not separate haemoplasm from haemocytes[11,19,20]. Too low a centrifugation speed, however, will contaminate the haemoplasm with L-glutamate from the haemocytes. Too high a centrifugation rate on the other hand,

Table 2 Reaction products following treatment of glutamine with various protein precipitants

Treatment	Glutamate	Pyrrolidone carboxylic acid
70% Ethanol	0.3–0.8	1.2–1.7
3% Sulphosalicylic acid	2.0–4.3	2.13–5.93
15% Trichloroacetic acid	0.2–2.2	0.83–5.43
0.4 N Perchloric acid	0.7–1.0	0.83–4.62
12-h-old 0.4 N Perchloric acid	10.1–11.0	10.93–11.73
1-week-old 0.4 N Perchloric acid	14.0–18.0	13.23–17.63

Glutamate and pyrrolidone carboxylic acid are expressed as percentage produced from hydrolysis of 10^{-3} M glutamine. Incubation of glutamine with protein precipitants was for 10 min in an ice bath. The 'aged' perchloric acid had been kept at room temperature. Range given from five separate determinations. The percentages of glutamate and pyrrolidone carboxylic acid formed vary greatly and the above figures should not be taken as absolute but merely as an indication that the reaction occurs.

causes haemocyte rupture, with consequent release of L-glutamate into the haemoplasm.

(4) Other tissues have a high concentration of L-glutamate[14] which may contaminate the haemoplasm during extraction.

Thus our results show that L-glutamate is virtually absent from arthropod haemoplasm, or if detected, exists in concentrations which are far below those measured by other workers. We believe that this new finding resolves one of the major obstacles to the acceptance of L-glutamate as a neurotransmitter at arthropod somatic nerve–muscle junctions. Further details of this work will be published elsewhere.

We thank Dr J. Fox for discussion and sample analysis, Dr M. Wilkinson for use of HVPE equipment, and Dr C. Potter for helpful discussion. One of us (S.N.I.) acknowledges financial support from the SRC and Wellcome Research Laboratories.

Influence of social setting on the induction of brain cyclic AMP in response to electric shock in the rat

RATS subjected to electric footshock display two disparate behaviours, Escape-attempts or aggressive attack, depending on whether the rat is shocked alone or with a conspecific[1]. Different responses in blood pressure[1], ACTH levels[2], and brainstem noradrenaline turnover[3] develop in these two patterns of behaviour. On the basis of these studies we hypothesised an additional differential response for brain cyclic AMP levels. We now report a 100% increase in whole brain cyclic AMP following shock-induced fighting but not after identical footshock given to isolated rats. This increase occurred with or without systemic pretreatment of the rats with caffeine, an inhibitor of phosphodiesterase, the enzyme which deactivates cyclic AMP.

Forty-eight male Sprague–Dawley rats (180–220 g, Simonsen, Gilroy, California) were individually housed with *ad libitum* access to food and water and then randomly assigned to one of six experimental groups. These were a control group; a saline-injected control group; a shock-alone (Escape-attempt) group; a shock-paired (Fighting) group; a caffeine-treated group, unshocked; and a caffeine-treated group which was shocked when paired (Caffeine-Fighting). After two weeks of habituation to their environment the rats were exposed to testing. Those rats which received

footshock either alone or in pairs received, within a Plexiglas enclosure, 50 2-mA footshocks of 0.4 s duration with a fixed intershock interval of 7.5 s. This procedure and apparatus have been described in detail elsewhere[4,5]. Rats did not successfully avoid the footshock and all rats, whether alone or paired, subjectively appeared to sustain comparable levels of shock as indicated by vigorous vocal and skeletal motor responses. All shocked groups were tested for 3 consecutive days in the morning.

Groups receiving drugs were injected approximately 30–60 min before behavioural testing, or at the end of the study, before killing. The saline group received 0.9% saline, intraperitoneally in a 2-ml volume, for 3 d. The caffeine groups received caffeine given as the citrate in a dose of 100 mg kg^{-1}, in a 2-ml volume, also for 3 d.

Immediately following the third day of testing and treatment, each rat was killed by microwave irradiation, in order to rapidly denature the enzymes responsible for the synthesis (adenylate cyclase) and degradation (phosphodiesterase) of cyclic AMP. The microwave apparatus used was a model 4104 Metabostat (Gerling Moore), with a power output of 5 kW at a frequency of 2,450 MHz. Animals which were shocked, either alone or paired, (with 50 footshocks during a 6.2-min period), were killed between 2–5 min after the cessation of footshock. For irradiation, rats were placed in a cylindrical animal holder. This holder allowed the rats to assume a relatively natural position and placed only the head in the microwave field. There were no difficulties with animal excitation. Irradiation for 1.5 s produced rapid and uniform heating of all brain areas. All control and caffeine-injected rats were killed in the same manner. After irradiation, brains were quickly removed from the skull, frozen on dry ice, and stored at −70 °C until analysed. Tissues were homogenised in 5% TCA, containing a known amount of tritiated cyclic AMP to monitor nucleotide recovery during purification. Cyclic AMP was assayed according to a modification of the competitive protein binding method as described by Tovey *et al.*[6] using a commercially available cyclic AMP-dependent protein kinase (Sigma).

Whole brain levels of cyclic AMP are presented in Table 1. The untreated-unshocked control group (C) had brain levels of 0.202 ± 0.011 (pmol cyclic AMP per mg of wet brain weight). The saline-injected unshocked group (S) had comparable levels of 0.206 ± 0.019. Either shock to rats alone (Escape-attempt) or the administration of caffeine to unshocked rats (CAF) elicited respective cyclic AMP levels of 0.243 ± 0.013 and 0.242 ± 0.027. Paired shocking of rats, eliciting shock-induced aggression, produced levels of cyclic AMP in the untreated (Fighting) and caffeine-treated (CAF–Fighting) groups of 0.445 ± 0.073 and 0.401 ± 0.021, respectively. A one-way analysis of variance for these data was significant at the $P < 0.005$ level ($F_{5,39} = 8.68$). Untreated shock-alone group (Escape-attempt) and the untreated shock-paired group (Fighting) significantly differed from the untreated-unshocked control group by two-tailed t test ($P < 0.05$ and $P < 0.01$ respectively). The caffeine-treated group, unshocked, did not significantly differ from the saline-injected group in this study. The shock-paired caffeine-treated group (Caffeine–Fighting) had significantly

Table 1 Levels of brain cyclic AMP (pmol per mg wet weight)

Group	N	cyclic AMP (mean ± s.e.m.)
C	7	0.202 ± 0.011
S	7	0.206 ± 0.019
CAF	7	0.242 ± 0.027
Escape-attempt	8	0.243 ± 0.013
Fighting	8	0.445 ± 0.073
CAF-Fighting	8	0.401 ± 0.021

elevated cyclic AMP when compared to the saline-injected (P <0.001) or caffeine-injected (P <0.05) unfought groups. There was no statistically significant difference between the uninjected or saline-injected control groups, or between the caffeine-treated or non-treated fighting groups. The un-injected Fighting group had markedly higher levels of cyclic AMP than the uninjected Escape-attempt group (P <0.02).

These results are in accord with other studies which have demonstrated physiological, neurohumoral, and neuro-chemical differences elicited by footshock when delivered to rats alone, inducing primarily attempted escape behaviour (a fear response) and when delivered in the presence of a conspecific, inducing fighting behaviour (an aggressive res-ponse). Williams and Eichelman demonstrated that the tail blood pressure of the rat decreased in the case of the Fighting paradigm and increased in the case of the Escape-attempt paradigm[1]. They also showed that the decrease could be selectively abolished by central destruction[7] or peripheral destruction (unpublished observations) of catecholamine neurones with 6-hydroxydopamine. Con-versely the increase of tail blood pressure in the Escape paradigm could be abolished with adrenalectomy (Williams and Eichelman, unpublished observations). Conner *et al.*[2] demonstrated that the Escape-attempt paradigm elicited greater ACTH secretion than the Fighting paradigm, con-sistent with the adrenal-blood pressure response noted by Williams and Eichelman. Stolk *et al.*[3] have reported that brainstem noradrenaline metabolism also differs in the two paradigms. Rats shocked on their own (Escape-attempt) demonstrate an increase in noradrenaline turnover in the medulla-pons during the shock period, whereas rats paired and fighting fail to demonstrate this and show an increase in noradrenaline turnover in the 1-h period after shock, which correlates with the number of attacks observed.

The enhancement of shock-induced fighting in the rat has been repeatedly associated with a facilitation of central catecholaminergic systems[8,9]. Studies in mice have shown interstrain differences in brain cyclic AMP which are genetically controlled and correlate closely with murine aggressive behaviour[10]. Additional evidence has accumulated to link cyclic AMP with central catechola-mine metabolism and behaviour[11]. The large increase in cyclic AMP with fighting is consistent with the multiple associations of aggression and cyclic AMP with central catecholamine metabolism. A potential causal and temporal relationship between the increase in cyclic AMP and in-creased noradrenaline turnover following fighting could be explored in future studies in the light of the increase in nor-adrenaline turnover following fighting observed by Stolk *et al.*[3].

The increase in cyclic AMP following footshock in the Escape paradigm should not be overlooked. It remains dwarfed, however, when compared with the magnitude of increase in the Fighting situation. Although our data in this study fail to demonstrate an increase in whole brain cyclic AMP after three daily injections of caffeine, it must be considered that an increase might have been statistically significant had a larger sample been used or a different time course for sacrifice chosen. Behavioural work[12] has shown that the greatest facilitation of shock-induced fighting following caffeine treatment occurs 4 h after injection. Caffeine given under the conditions of our study neither suppressed nor facilitated the induction of whole brain cyclic AMP; rather, the behavioural setting and the behaviour arising out of it appeared prepotent. Our findings may have further implications for understanding mam-malian coping and aggressive behaviour.

Spike after-hyperpolarisation of a sympathetic neurone is calcium sensitive and is potentiated by theophylline

IN many neurones, calcium as well as sodium enters during the action potential[1]. Intracellular injection of calcium has been shown in several neurones to increase membrane con-ductance to potassium[2,3], and voltage clamp experiments have demonstrated that inward calcium currents can acti-vate outward potassium currents[4-7]. The action potential in many nerve cells is followed by a slower after-hyper-polarisation (AH), which results from increases of one or more potassium conductances[8,9]. Therefore, calcium influx during an action potential might activate part or all of the subsequent AH[2,3,10]. A calcium-dependent component of the AH has been demonstrated so far in myenteric plexus neurones[11,12] and spinal motoneurones[13]. This component of the AH is blocked by Co^{2+}, Mn^{2+} and La^{3+}, which an-tagonise calcium influx[12,13], but agents that potentiate such AHs have not been reported. We have used sucrose-gap recording[14] to investigate the sympathetic ganglion of the bullfrog, and report here that the sympathetic neurones have a calcium-sensitive component of the spike AH. Fur-thermore, this calcium-sensitive potassium conductance is potentiated by theophylline, a drug known to affect cellular calcium metabolism.

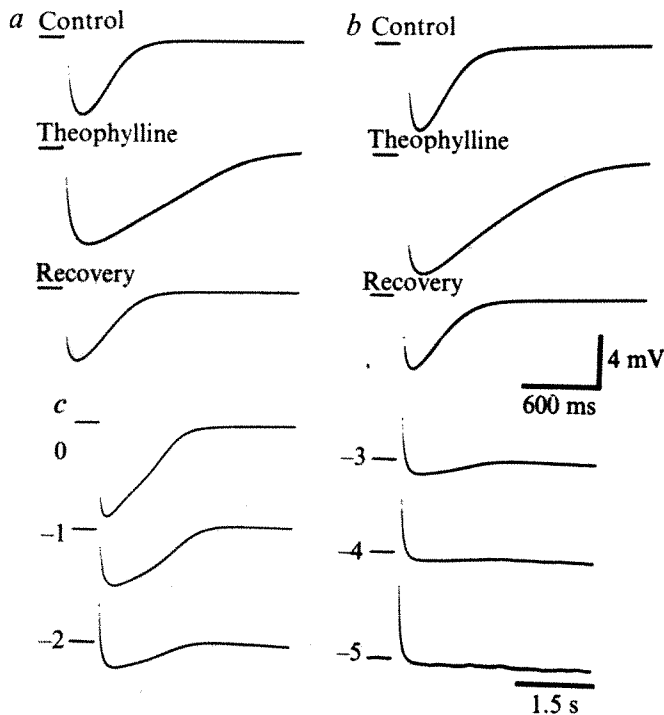
Figure 1 shows that 5 mM theophylline considerably and reversibly potentiated the action potential AH in the sym-pathetic ganglion. The AH was increased whether the action potentials were generated by orthodromic B (Fig. 1*a*) or C fibre stimulation or by antidromic stimulation of the cells (Fig. 1*b*). The predominant effect of theophylline was an enhancement of the AH duration. It increased the half-time for decay of the antidromically elicited AH up to 800%. The duration of the potentiated AH was inversely dependent on stimulus frequency, with maximal durations observed only when stimuli were administered more than 1 min apart. Theophylline enhanced the AH amplitude to a lesser extent, only increasing the peak amplitude of the antidromically elicited AH up to 150%. Additionally, theophylline often changed the AH shape from a smooth curve to one with an inflection point on the decaying slope (Fig. 2*b*) or, at times, to a biphasic W-shaped curve with early transient and late slow components. The AH reached maximum potentia-tion within 15 min of the introduction of the drug and


Fig. 1 Effect of theophylline on the action potential AH. *a*, Upper: AH of synaptically activated action potential. Preganglionic B fibres stimulated in the sympathetic chain rostral to the seventh ganglion with a single supramaximal stimulus. Middle: effect of theophylline on the AH 35 min after start of superfusion with Ringer solution containing 5 mM theophylline. Lower: AH 65 min after start of theophylline washout. *b*, Upper: AH of antidromically activated action potential. Postganglionic axons stimulated across the sucrose gap with a single stimulus. Site of stimulation at point where postganglionic axons exit ganglion and enter sucrose chamber. This is termed direct stimulation by Nishi and Koketsu[14]. Middle: effect of theophylline on the AH 30 min after start of superfusion with Ringer solution containing 5 mM theophylline. Lower: AH 60 min after start of theophylline washout. *c*, Electrical polarisation of theophylline-potentiated AH. Action potential elicited as in *a* and recorded 50 min after start of superfusion with Ringer solution containing 5 mM theophylline. Hyperpolarising current passed across sucrose gap[14]. Numbers to the left of each record indicate the hyperpolarising current $\times 10^{-6}$ A. Records in *a*, *b*, and *c* are from photographs of oscilloscope traces. Action potentials were lost in photographic reproduction. The experiments reported here were conducted on the tenth paravertebral ganglion of the bullfrog (*Rana catesbeiana*) by means of sucrose-gap recording[14]. The composition of the Ringer solution was (mM): NaCl, 100; KCl, 2; $CaCl_2$, 1.8; Tris-HCl, 16, pH 7.2; and glucose, 1 g l^{-1}. Calcium-free Ringer had the same composition except that $CaCl_2$ was omitted. The ganglion was continuously superfused with oxygenated Ringer solution.

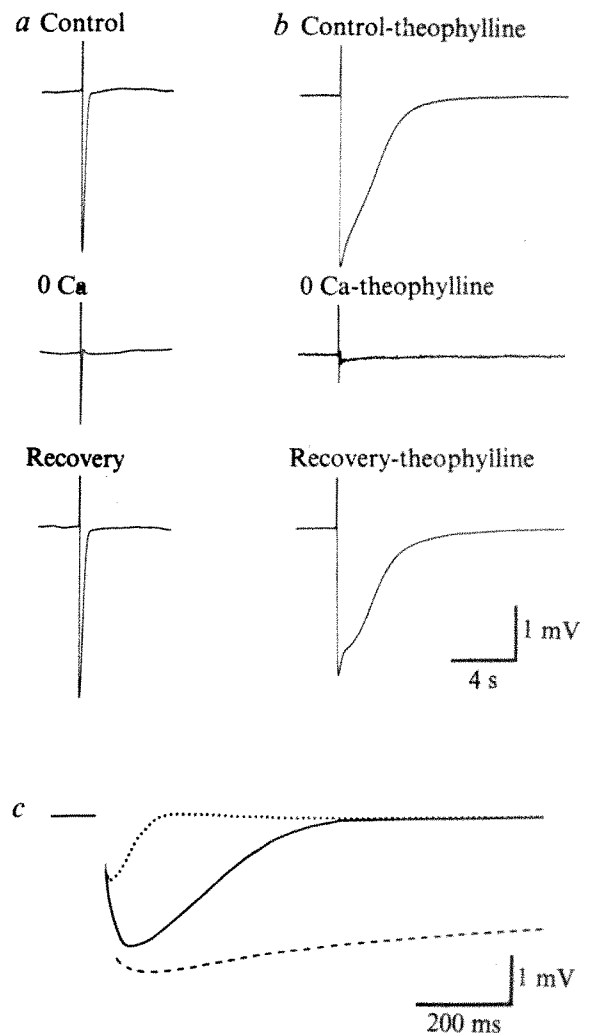
returned to control after superfusion with normal Ringer for 15–30 min. Theophylline did not significantly affect the amplitude of the action potential elicited by orthodromic stimulation. Stimulus artefact obscured the antidromically elicited action potentials.

Theophylline also potentiates the slow inhibitory post-synaptic potential (slow i.p.s.p.) in both bullfrog (our work, in preparation) and rabbit[15] sympathetic ganglia. It is therefore important to compare these two hyperpolarising potentials. The slow i.p.s.p. in bullfrog ganglia is generated by a decrease in sodium conductance and thus is potentiated by moderate hyperpolarising current[16]. On the other hand, the action potential AH in frog ganglion cells has been shown to be generated by an increase in potassium conductance, and thus is decreased by hyperpolarising current[17,18]. Figure 1c shows that moderate hyperpolarisation of the resting membrane potential progressively reduced and abolished the theophylline-potentiated AH. Amplifier limitations prevented the passing of further hyperpolarising current. Furthermore, although atropine (1 μg ml^{-1}) blocks the slow

i.p.s.p.[19], it does not affect the theophylline-potentiated AH. These data distinguish the theophylline-potentiated AH from the slow IPSP and suggest that the potassium conductance during the AH is prolonged by theophylline.

The theophylline-induced potentiation of the AH was abolished by the removal of extracellular calcium. This was shown in two ways. First, as illustrated in Fig. 2b, the ganglia were superfused with a Ringer solution containing normal calcium and 5 mM theophylline until maximal AH potentiation occurred. Then they were superfused with Ringer containing theophylline but no calcium. As can be seen, the AH was markedly diminished in duration and amplitude, becoming even smaller than the pre-theophylline control. The potentiated AH returned when calcium was

Fig. 2 Effect of calcium-free Ringer solution on normal and theophylline-potentiated AH. *a*, Normal AH. Upper: AH of antidromic action potential; Middle: effect of calcium-free (0 Ca) Ringer 43 min after start of superfusion with calcium-free Ringer solution; Lower: recovery record 10 min after return to Ringer solution containing normal calcium. *b*, Effect of calcium-free Ringer on theophylline-potentiated AH. Upper: AH of antidromic spike potentiated by 5 mM theophylline; Middle: effect of calcium-free (0 Ca) Ringer containing 5 mM theophylline 33 min after start of superfusion with calcium-free Ringer solution; Lower: recovery record, 11 min after return to Ringer solution containing normal calcium and 5 mM theophylline. Records in *a* and *b* from rectilinear pen recorder (Brush Model 280). Transient depolarisation consists of stimulus artefact and action potential; it was truncated for purposes of illustration. *c*, Effect of theophylline and calcium-free Ringer on AH on expanded time scale. ————, Normal AH of antidromic spike; ...., effect of calcium-free Ringer on normal AH; — — — — —, effect of 5 mM theophylline on normal AH. Tracings of oscilloscope records. From the same experiment as *a* and *b*.


restored. Second, ganglia were superfused with calcium-free Ringer for more than 4 h. At that time the addition of 5 mM theophylline did not significantly alter the antidromically elicited AH.

Figure 2a shows that the AH elicited by antidromic stimulation in normal Ringer decreased in duration and amplitude during superfusion with calcium-free solution. This effect was reversed on readdition of calcium to the superfusate. The AH elicited in calcium-free Ringer resembled that elicited in 5 mM theophylline-calcium-free Ringer (Fig. 2b) although there was some variability in the comparative amplitudes from experiment to experiment.

Figure 2c compares the AH, on an expanded time scale, in calcium-free Ringer, in normal calcium Ringer, and in normal calcium with 5 mM theophylline, as recorded by the sucrose gap[14]. This technique records the membrane potentials of the population of ganglion cells. In experiments with intracellular recording from sympathetic ganglion cells, the removal of extracellular calcium markedly decreased the duration but not the amplitude of the AH (our unpublished observations with J. Schulman). This suggests that the decrease in AH amplitude in calcium-free Ringer recorded by the sucrose-gap technique is due to the summation of a temporally dispersed population response.

Our data show that the repolarisation phase of the AH in frog sympathetic ganglion cells depends on extracellular calcium. Koketsu and Nishi[20] demonstrated previously that calcium as well as sodium can enter these neurones during an action potential. This suggests that calcium influx during the action potential activates a potassium conductance that prolongs the duration of the AH. Alternatively, calcium influx may control the rate of inactivation of the AH potassium conductance. In the experiments reported here, we also found that theophylline greatly potentiated the calcium-sensitive potassium conductance. Theophylline may increase the stimulus-induced entry of calcium into these neurones, as it does in other tissues[21,22], thus augmenting the activation of the potassium conductance; however, we cannot exclude other possibilities, for example that theophylline enhances the calcium sensitivity of the AH potassium conductance.

Theophylline inhibits cyclic nucleotide phosphodiesterases and potentiates cyclic nucleotide-dependent processes in many tissues[23]. Cyclic nucleotides may be involved in cellular calcium metabolism[24,25] and could play a role in the augmentation of the AH by theophylline. In cardiac Purkinje fibres theophylline and cyclic AMP increase both a slow inward current carried by calcium and sodium and a slow outward current carried predominantly by potassium[22].

Calcium-sensitive potassium conductances modulate the excitability and the repetitive firing of neurones[4,10,13,26]. Theophylline may therefore prove to be a useful tool for investigating regulation of neuronal activity and responsiveness.

We thank J. A. Nathanson, J. A. Schulman and P. A. Smith for helpful discussions.

Phosphorylation of myelin basic protein by vaccinia virus cores

PROTEIN kinases, catalysing the transfer of the γ phosphate from ATP to serine and threonine residues in protein substrates have been described in several enveloped viruses[1-3]. Vaccinia virus contains a protein kinase that has recently been well characterised[4]: it is located within the viral core, is not stimulated by cyclic mononucleotides and phosphorylates at least two viral acceptor proteins. The biological functions of the protein kinase and acceptor proteins are unknown, but it is possible that the viral protein kinase could also act on host proteins, thus providing a mechanism by which the virus could modify or control host processes on infection[1]. Vaccinia virus can induce a demyelinisation after experimental infection, but the mechanism for this is poorly understood[5]. It has been suggested that direct viral action on membranes may have a role in the pathogenesis of virus-induced demyelinisation[6]. We have therefore investigated the ability of vaccinia virus cores to phosphorylate human myelin membranes in an *in vitro* system and report here that they can phosphorylate purified myelin basic protein as well as basic protein in the myelin sheath.

Purified myelin basic protein was found to be an excellent substrate for the core-associated protein kinase (Figs 1 and 2a). No activator was needed, which suggests that myelin basic protein functions both as an activator and as a substrate[4]. The almost quantitative recovery of the radioactivity from the TCA experiments (Fig. 1) in the peak corresponding to the myelin basic protein on SDS gel (Fig. 2a), shows that the more than tenfold increase in ^{32}P-incorporation observed with added myelin basic protein, compared with core alone, represents phosphorylation of the myelin basic protein and not an increase in ^{32}P-incorporation in core proteins. It is possible that part of the phosphorylation of soluble myelin basic protein might actually be phosphorylation of histone contaminants. This seems rather unlikely, however, because the myelin basic protein used migrated as a single band on disc gel electrophoresis at acid *p*H and radioactivity was found only in the slices corresponding to the myelin basic protein on polyacrylamide gel electrophoresis in sodium dodecyl sulphate (SDS) (Fig. 2a). The addition of cyclic AMP or 8-bromo cyclic AMP (a cyclic AMP analogue more resistant to phosphodiesterase) did not stimulate the reaction (data not shown). Following a 1-h incubation, a total of 0.5 mol of phosphate was incorporated per mol of myelin basic protein. Determination of the isoelectric point of the myelin basic protein, by extrapolation to zero of the (*p*H-dependent) mobilities on analytical cellulose acetate sheets[11], showed a significant change in the isoelectric point from 10.8 for the native myelin basic protein, to 10.4 for the phosphorylated protein. The phosphorylated fraction was eluted from the cellulose acetate strip and contained 1 mol of phosphate per mol of myelin basic protein.

So far, the demonstration of a direct phosphorylation of host-cell components by a viral protein kinase has been hampered by the high level of endogenous protein kinase activity present in most *in vivo* or *in vitro* systems[12]. This endogenous activity

present in myelin membranes in our system can be completely inactivated by mild heating[10,13]. We have shown that such heated membranes can be used as a substrate for exogenous enzyme[10], thus allowing us to test the ability of the core-associated protein kinase to phosphorylate the myelin basic protein in an environment reflecting the native structural state. Using such heat-inactivated myelin membranes there was a significant increase in ^{32}P incorporation with added myelin membranes, compared with core alone (Fig. 1). Analysis of the phosphorylated products on SDS–polyacrylamide gel electrophoresis (Fig. 2b) shows incorporation of radioactivity over the band corresponding to the myelin basic protein. It is interesting that the viral protein kinase shows the same specificity as the endogenous protein kinase of myelin[10], because the other major myelin proteins show no incorporation of radioactivity.

We observed a much lower phosphate incorporation with myelin membranes than with isolated myelin basic protein. After incubation for 60 min, 29.7 nmol ^{32}P-phosphate per mg myelin basic protein was incorporated when isolated myelin basic protein was used as a substrate and 4.25 nmol when myelin membranes were used. Steric factors must therefore play a major part in the incorporation of ^{32}P, since our system can be compared with a solid-state reaction between the enzyme, bound to the large viral core (molecular weight $\sim 2 \times 10^9$) and the membrane-associated substrate. In the final step of our core preparation non-ionic detergents were removed, to prevent

Fig. 1 Time course of ^{32}P incorporation with core alone (▲), core and heat-inactivated myelin membranes (■) and with core and isolated myelin basic protein (●). The reaction mixture[7], with a final volume of 250 µl contained 50 mM Tris-HCl, pH 10.25, 5 mM dithiothreitol, 5 mM MgCl$_2$, 0.5 mM γ-^{32}P-ATP (30–90 c.p.m. pmol^{-1}), 30 µg of core protein and either ~100 µg of heat-inactivated myelin protein or 30 µg of purified myelin basic protein. Incubations were carried out at 34 °C. Reactions were terminated with 2.0 ml of 10% trichloroacetic acid (TCA) containing 0.06 N sulphuric acid. The material was collected on Millipore filters (0.45 µm), washed extensively, dried and counted in 10 ml of Aquasol in a liquid scintillation counter. Separate blank values, determined for different substrates, were always subtracted. Incubation of heat-inactivated myelin membranes alone for up to 1 h with the total reaction mixture gave the same value as the corresponding zero blank with added enzyme. Vaccinia virus (strain WR) and cores were prepared by slight modifications of the procedure described by Paoletti and Moss[7]. Myelin was prepared from human brain (white matter) by the method of Norton[8]. Heat inactivation was at 55 °C for 5 min and any broken membranes were removed by recentrifuging the heated membranes over a discontinuous sucrose gradient and collecting only the material banding at 0.85 M sucrose. Myelin basic protein was prepared from bovine brain[9] using Cellex-P column chromatography as a final step.

Fig. 2 Absorbance (—) of 7.5% polyacrylamide gel in 0.1% SDS and the corresponding radioactivity of ^{32}P-phosphorylated products (●). Arrow denotes myelin basic protein. The reaction mixture is as described in Fig. 1 but with a final volume of 1,000 µl; incubation was for 60 min at 34 °C. a, Incubation mixture contained 120 µg of purified myelin basic protein and 120 µg of core protein. At the end of the incubation, the mixture was cooled on ice, transferred in a centrifugation tube and the core pelleted through 0.85 M sucrose. The supernatant, containing the myelin basic protein, was collected, precipitated with TCA, washed with ethanol–water 9:1 and the resulting pellet solubilised for electrophoresis as described previously[10]. About 10 µg of protein was applied for electrophoresis. b, Incubation mixture contained 400 µg of heat-inactivated myelin membranes (prepared as described in Fig. 1) and 120 µg of core protein. After incubation the mixture was ice cooled, transferred in a centrifugation tube and the core pelleted through 0.85 M sucrose. The myelin banding at 0.85 M sucrose was collected and solubilised for electrophoresis. About 100 µg of protein was applied for electrophoresis. Preparation of gels, staining and destaining were as described previously[10]. Gels used to measure radioactivity were cut into 2-mm slices and the fractions solubilised in a toluene-based scintillation fluid containing a solubiliser (Protosol). Blank values obtained for the different substrates without enzyme were subtracted. Scanning was at 530 nm using a Zeiss spectrophotometer fitted with a linear transport accessory. The results shown are representative of three different preparations. Note the difference in the scale of the ordinate between a and b.

any solubilisation of core components. *In vivo*, however, the core dissolves during infection with the subsequent release of its components[14]. Very little is known about the fate of many of the viral enzymes, but it has been shown that virus-induced modification of host membranes is not dependent on virus multiplication, host RNA or protein synthesis[6]. It is thus tempting to speculate that phosphorylation of myelin membranes by an enzyme system that is not dependent on endogenous concentration of cyclic nucleotides may occur *in vivo*. This might have a profound effect on myelin structure and function.

As regards the biochemical mechanisms of pathogenesis, the role of the viral protein kinase may involve action on: (1) myelin basic protein, (2) nuclear histones or (3) mitochondrial cytochrome *c*, since the enzyme shows a strong proclivity for basic proteins[7] and is not specific to myelin basic protein. Whether the phosphorylation of the myelin basic protein, an encephalitogenic protein, by the vaccinia core-associated protein kinase, is relevant to the demyelinisation observed after experimental vaccinia virus infection remains to be determined.

Ribonuclear protein formation at locus *2-48 BC* in *Drosophila hydei*

In *Drosophila hydei* salivary glands, a puff can be induced by treatment with vitamin B[6] (ref. 1) at locus *2-48 BC*. This puff is one of the series that can also be induced by temperature shock, anaerobiosis or treatments interfering with the respiratory metabolism[2]. A product of this puff seems to be a giant ribonucleoprotein (RNP) complex (diameter up to 4,000 Å) with a very specific morphology[3]. This complex consists of a core and a cortex, formed by a wreath of small particles (diameter approximately 300 Å; ref. 4). Cytochemical analysis has shown that the core of the complex is essentially free of RNA whereas the cortex does contain RNA[4]. Using phospho-tungstic acid (PTA) as a specific stain for proteins, it could also be shown that the proteins from the cortex are relatively rich in arginine and lysine residues whereas those in the core are relatively poor in such residues[5]. No similar puff product has so far been found in any other locus of *D. hydei*. In addition to the giant RNP complexes small RNP particles (diameter up to 300 Å; not to be confused with the particles from

Fig. 1 Staining of RNP from locus *2-48 BC* in puff and nucleoplasm (insets). *a*, *b* and *c*, RNP particles and complexes in puff *2-48 BC*. Magnifications: *a*, *b* and *c*: ×15,360; insets: ×48,000. Glands were isolated by hand. Puffs were induced by incubation for 3 h in Poels medium containing 5×10^{-2} M vitamin B[6] (ref. 1). After fixation in 3% glutaric aldehyde in sodium cacodylate buffer (*p*H 7.2) for 30 min at 4 °C, followed by 1 h at room temperature, glands were dehydrated and embedded in Epon[8], sectioned with an LKB ultratome III and examined using a Philips EM 201. Stainings were as follows: *a*, 3% aqueous uracil acetate for 10 min and subsequently for 0.5–1 min in alkaline lead citrate[9]; *b*, after fixation and dehydration, with 3% PTA in ethanol at 0 °C overnight[10]; after washing twice with cold ethanol, glands were embedded and sectioned as described above; *c*, fixation and washing (twice) with distilled water; staining with 5% aqueous PTA (adjusted to *p*H 1 with concentrated HCl) for 3 h at room temperature (modified from Palladini *et al.*[11]), followed by three rinses with distilled water, dehydration, embedding and sectioning as described above.

the cortex) can also be seen in this puff[2,5]. A comparison of data from both ultrastructural and autoradiographical studies on RNA formation at locus *2-48 BC* has led to the conclusion that the small RNP particles present in this puff aggregate to the giant RNP complexes and thus give rise to the final puff product[6]. This conclusion is in agreement with the finding of a single RNA species in puffs obtained by microdissection of salivary glands[7]. Although the small RNP particles in the puff have not been studied extensively, it has been assumed that, based on the presence of RNA and arginine and lysine residues, the small particles form the cortex of the complex[5], leaving the origin of the cortex proteins still obscure. Here I present the results of a comparison between the staining of the small RNP particles with that of the components of the giant complexes. These studies indicate that the same components of the small RNP particle become part of the core of the complex after aggregation.

After induction of puff *2-48 BC* with 5×10^{-2} M vitamin B[6], glands were prepared for electron microscopy. A comparison was made between staining with uracil acetate–lead citrate (on grids), PTA in ethanol (on block) and aqueous PTA at *p*H 1 (on block), (Fig. 1). The results are summarised in Table 1.

It is clear that with all the three staining methods the small RNP particles stain densely. The staining with PTA was independent of the presence of RNA since neither RNase treatment (on block, followed by a mild TCA extraction), nor alkaline (0.1 M NaOH for 24 h at 25 °C) nor acid (TCA 5%, 24 h at 25 °C) hydrolysis markedly affected the staining. Thus the proteins in the small RNP particles in the puff can bind PTA in alcoholic as well as in aqueous solutions at *p*H 1. In the complex the proteins attached to the RNA in the cortex can still bind PTA in alcoholic solutions but the binding

Table 1 Staining intensity of RNP particles present in locus *2-48 BC*

Stain	Small RNP particles	Giant complexes Core	Cortex
Uracil acetate–lead citrate	+++	+++	+++
PTA, alcohol	+++	−	+++
PTA, aqueous	+++	+++	+

capacity for PTA in aqueous solutions is largely lost. The proteins in the core of the complex cannot bind PTA in alcoholic solutions, but do bind, like the small RNP particles, PTA in aqueous solution. From these data it can be inferred that, during aggregation, the small RNP particles lose an aqueous PTA-binding protein that is found later, after aggregation, in the core of the complex. The proteins in the core of the complex must therefore be assumed to derive, at least in part, from the small RNP particles. Other explanations for these observations, such as an exchange of RNP proteins with nucleoplasmic proteins, remain possible but are unnecessarily complicated. Moreover, structures resembling the core of the complex have never been observed separate from the complex. Since, in this kind of study, the available techniques do not permit quantitative analysis on the ultrastructural level, no conclusion can be drawn with respect to the amount of protein involved in the formation of the core of the complex. The presence in the complexes of nucleoplasmic proteins, besides the proteins derived from the RNP particles, cannot be excluded.

Since the giant complexes can be found in a well defined area within the puffed region[2,5], an involvement of the genome in the aggregation process could be postulated, but no evidence for such an involvement is available. So far, data concerning a possible function of the aggregation process and the proteins involved in it are also lacking. Such an analysis must await biochemical analysis of isolated complexes. It is not clear to what extent the changes in protein composition in this particular RNP product can serve as a model for RNP formation in general but the formation of this special gene product shows that RNP production can be very complicated, more so than is generally understood from the biochemical data available at this moment.

I thank Dr N. H. Lubsen for comments.

Long range homogeneity of physical stability in double-stranded DNA

WE present here evidence for the existence of regions with homogeneous physical stability (homostability regions) in double-stranded DNAs. Results of a study on the thermal melting of whole replicative form DNA from fd phage and of its fragments obtained by the action of restriction enzymes, strongly suggest that regional homostability seems to be an intrinsic characteristic of DNA, playing an essential part in its genetic activities.

A sequence of A–T and G–C paired bases that stabilises two nucleotide chains into one double-helical conformation is responsible for both the biological and physical characteristics of DNA; that is, the genetic information is 'written' by a variation of that sequence on the one hand, and the physical stability of the double-stranded structure is determined by the base composition on the other hand. An

indication of the second characteristic is that the melting temperature is known to increase with the G+C content. These properties of double-stranded DNA open up a possibility of probing the genetic structure by means of purely physical observations.

A series of studies on the local stability of a DNA has been carried out by a thorough measurement of hyperchromicity caused by the unfolding of the double strand with increasing temperature. Several distinctive features which have been obtained are : (1) Thermal melting is not a continuous process, but consists of a set of discrete steps (refs 1–4 and refs therein). In the case of a relatively short DNA such as λ-DNA (46,000 base pairs), it appears as several sharp peaks over a broad background in a differential display, each of which corresponds to a unit or units of melting having the same stability. (2) Spectral analysis of each peak has shown that the local G+C content in the homostability region is a major determining factor of its melting temperature (C. Akiyama, O.G., and A.W., unpublished). The Marmur–Doty relationship between the melting temperature and G+C content for whole DNA, also holds for localised melting within a DNA molecule. (3) The homostability regions also exist in long DNAs (ref.

Fig. 1 A, Melting profile of whole DNA (RF-linear) of fd phage; B, after digestion by RHinHI; that is, a mixture of HinHA+HinHB+HinHC (bold solid line); C, profiles of separated fragments, HinHA (white area), HinHB (hatched area) the and HinHC (black area), respectively. The scales of the A are same as B and C. Buffer solution: 0.1 × SSC. Doubly closed replicative form (RF) DNA of fd phage was cleaved by three different restriction enzymes (RHindII, RHinHI, RHapII), and linear RF DNA produced by RHindII, three fragments produced by RHinHI (HinHA, HinHB, HinHC), and the longest fragment produced by RHapII (HapA) were prepared as in ref. 5. Top right, the HindII cleavage site and region covered by each fragment are indicated together with an approximate location and size of fd genes[6-8]. (Roman numerals indicate the gene number.) Melting profiles were obtained with a minicomputer controlled on-lined melting plotter[3]. The displays are made in the differential form d(1−θ)/dT against T, where θ is helix content, T temperature, and (1 − θ) for the fragments is defined as (1 − θ) = (1 − θ)×(length of fragment/length of whole DNA).
Fig. 2 Melting profiles of *HapA* (○), and of *HinHC* (●) fragment which is totally involved in *HapA*.

4 and O.G., S. Yabuki and A.W., unpublished), although the fine structures in the melting profile become obscure, probably because of random overlapping of the clustered peaks. The existence of the homostability region seems to be a general attribute of the DNA. (4) Studies on the DNA from deletion mutants have shown that a single peak in the melting profile can result from the melting of one or several homostability regions[2,3]. (5) From a computer simulation for model DNAs of given sequences[3], it is strongly suggested that a long range homogeneity in the base sequence (>500 base pairs) is necessary to produce a single sharp peak similar to those observed in our experiment. Here "homogeneity" does not mean either a regularly repeated sequence or homopolymers, but refers to a fairly long sequence consisting of over 500 base pairs in which A–T and G–C pair sequences alternate at frequent intervals made up of no more than a few base pairs[3].

In addition to the facts mentioned already, much new evidence, obtained with a much shorter DNA from fd phage and its fragments made by restriction enzymes[5], have made the characteristics of regional homostability much clearer.

The most distinctive feature of the differential melting profile of the whole fd-DNA (RF-linear; 6,000 base pairs) is that all the peaks are very sharp and well separated from one another (Fig. 1*A*). By the action of the restriction enzyme R*Hin*HI on the DNA (RF-circular), the melting profile changes to yield a set of different, but still sharp and well separated peaks (Fig. 1*B*, bold line). The individual melting profiles of each digestion product, *HinHA* (~3,500 base pairs), *HinHB* (~1,800 base pairs), and *HinHC* (~700 base pairs), were measured after separation by gel electrophoresis, and are shown together in Fig. 1*C*. The genetic map is also shown, to allow location of the fragments in it[6-8]. These three digestion product melting profiles, when summed, are found to agree with the profile of the mixed DNA (Fig. 1*B*). There are, however, not quite additive enough to reproduce that of the whole DNA (RF-linear) (Fig. 1*A*). Figure 2 shows the melting profile of *HapA*, the fragment produced by a different digestion process, compared with *HinHC*, and from the map shown in Fig. 1, *HinHC* is totally involved in *HapA*.

These experimental results from the fragments indicate that the homostability region is not uniquely defined by short range stability of the double-stranded DNA. A long range interference between the homostability regions may come through the loop entropy and electrostatic interaction of the melted region between them.

From the results, together with the genetic map, we may now conclude the following. (1) The DNA is found to consist of a number of homostability regions which come from

homogeneous base sequences consisting of 500 base pairs or more. (2) One genetic unit (the operon) may contain one or a few homostability regions. (3) Sometimes different genetic units have homostability regions with the same degree of stability. (4) A homostability region exerts the influence of the melting to other regions away from it, which sometimes produces splitting or coalescence of peaks. For instance, the highest peak of *HinHA* splits into two peaks in the profile of whole DNA, probably because of cleavage by R*Hind*II.

Location of the homostability regions on the DNA and the elucidation of the mechanism of interactions among these regions are an interesting subject for the study of the statistical mechanics of DNA chains.

Biologically, it is hard, if not impossible, to believe that such regional homostability originates in a fundamental characteristic of the genetic code itself. It is quite plausible, however, that the homostability region plays an important part somewhere in the biological process within which the DNA is closely related. If so, then the evolutionary selective force can be considered to have fixed such regions in DNA. From the size of the homostability region, recombination[9] might be one possible process which is aided by it. In any case, the wobble bases must give the necessary redundancy to make a homostability region without spoiling the biological meaning of the genetic code: the activity of proteins.

Specific cleavage of chloroplast DNA from higher plants by *Eco*RI restriction nuclease

THE physicochemical properties of chloroplast (cp)–DNA in higher plants have been reported[1-4]. Cp–DNAs occur as closed circles of molecular weight 85×10^6–97×10^6. Specific identification of cp–DNAs isolated from different plants cannot, however, be carried out on the basis of buoyant density, melting points, kinetic complexity or direct length measurement by electron microscopy, since each of these techniques give values which fall within narrow limits, and only overlap with one another a little[1,2].

The analysis of restriction nuclease digests by gel electrophoresis provides a very sensitive test to compare small DNA molecule species[5]. This technique has been applied successfully to various animal mitochondrial DNAs[6] and to mt–DNA of wild and petite yeasts[7]. We show here that
Fig. 1 Agarose gel electrophoresis of *Eco*RI digest of cp-DNAs from leaves of: *a*, pea; *b*, spinach; *c*, tobacco, *N. tabacum* var. Samsun; *d*, maize; and *e*, wheat. λ*plac*5 DNA digest (*f*) was used as a standard for molecular weight determination. The arrow indicates the direction of electrophoresis. Isolation of chloroplasts, DNA extraction from DNase-treated organelles and two-step CsCl ethidium bromide (or propidium di-iodide) gradient centrifugation of cp-DNA have been described previously[2]. The drug was removed using freshly redistilled butanol saturated with 0.01 M EDTA *p*H 8. DNA samples were then dialysed against three 500-ml changes of 0.1 M NaCl, 0.05 M Tris, 0.01 M EDTA *p*H 8.0. The cp-DNAs were pelleted at 35,000 r.p.m. for 10 h in a SW41 rotor after adjusting the NaCl concentration to 1 M. cp-DNA pellets were then dissolved in 0.1 M Tris, 0.001 M EDTA *p*H 7.5 and cleared by centrifuging for 30 s at 20,000*g*. The yields were about 30–50 μg of supercoiled cp-DNA per 100 g of leaves, depending on the plant species. DNA samples were analysed for purity and concentration by analytical CsCl gradient and were checked for circularity by electron microscopy[8]. To 20 μl of purified cp-DNA (2–3 μg DNA) were added 20 μl of 0.1 M Tris, 0.03 M MgSO$_4$ *p*H 7.5 and 5 μl of *Eco*RI endonuclease (enough enzyme to give a limit digest of 10 μg of λ DNA). Digestion was carried out at 37 °C for 3 h. The reaction was stopped by addition of EDTA to a final concentration of 15 mM and cooling to 4 °C. Each sample was treated with one volume of water-saturated phenol. Solid sucrose was added up to 20% and samples were layered on top of cylindrical 0.7% Agarose gels (type I, Sigma), 8 mm in diameter and 35 cm in length. Electrophoresis was carried out in 0.05 M Tris, 0.02 M Na-acetate, 0.002 M EDTA *p*H 8.05 (with glacial acetic acid) plus 0.18 M NaCl (ref. 5) at 100 V for 15 h, by which time, the bromophenol blue marker is ∼ 4 cm from the bottom of the gel. Gels were extruded gently from the plastic tubes and stained in darkness for 2 h in the electrophoresis buffer supplemented with 1 μg ml^{-1} ethidium bromide. They were than layered on a black background, illuminated at 254 nm with a Camag TL 900 ultraviolet lamp and photographed through an orange glass filter (Wratten 77 A) on Kodak Tri X 35-mm film. Microdol X was used for development (10 min).

cp–DNA extracted from different higher plants can be characterised and distinguished easily by gel electrophoresis of *Eco*RI digests.

Pisum sativum var. très hatif Annonay nain, *Spinacia oleracea* var. Monstrueux de Viroflay, *Nicotiana rustica* var. Pavonii, *Nicotiana tabacum* var. Samsun, *Nicotiana glauca*, *Zea mays* var. INRA 200, *Triticum aestivum* var. Capitole, were grown in a greenhouse. Chloroplasts were extracted from leaves (deribbed for spinach and tobacco) and cp–DNA isolated from DNase-treated cp-pellet according to a procedure already described[2], except that the two-step differential centrifugation used in organelle purification was repeated. The supercoiled cp–DNA was isolated as the lower ultraviolet fluorescent band of ethidium bromide (or propidium di-iodide) CsCl gradients. cp–DNAs were concentrated by pelleting after removal of drug and the purity was checked by analytical CsCl gradients (unimodal distribution). Control of circularity was achieved by Klein-schmidt spreading and positive staining with acid-alcoholic uranyl acetate[8]. The purified cp–DNAs were then digested by *Eco*RI endonuclease and the digest analysed by electrophoresis on 0.7% Agarose cylindrical gels. The *Eco*RI restriction fragments of λ*plac*5 DNA were used as mol-

ecular weight standards[5]. Gels were stained with ethidium bromide and ultraviolet fluorescence photographs were taken.

Figure 1 shows the electrophoretic pattern of the cp–DNAs isolated from pea, spinach, tobacco (*N. tabacum* var. Samsun), maize and wheat. Some 30 distinct bands were resolved in each case, about 25 moving more slowly than, or with, the bromophenol dye. The same number of bands was obtained whether electrophoresis was achieved on 35-cm or 60-cm Agarose gels. The cp–DNA of a given plant seems to be characterised by a specific digestion pattern and so may be easily distinguished from that of other plants belonging to different genera.

The characteristic band patterns of various cp–DNAs isolated in this way from several higher plants were found to be easily reproducible. For example, several independent preparations of cp–DNA have been made for each plant mentioned above. Separate digestions of these cp–DNAs were performed and the resulting band patterns found to be invariant. Identical patterns were obtained for a given plant with incubation times of cp–DNA in the presence of the *Eco*RI enzyme ranging from 1 h to 6 or 12 h.

The molecular weights of *Eco*RI fragments from

Fig. 2 Agarose gel electrophoresis of *Eco*RI digests of cp-DNAs from deribbed leaves of *a*, *Nicotiana rustica* var. Pavonii; *b*, *Nicotiana tabacum* var. Samsun; *c*, *Nicotiana glauca*; *d*, native cp-DNA of *Nicotiana tabacum* var. Samsun, a small spot (Star) of ethidium bromide was superimposed on the bromophenol blue before taking the ultraviolet photograph. Arrow indicates the direction of electrophoresis. Isolation of cp-DNAs, endonuclease digestion and electrophoresis of DNA fragments were performed as described in Fig. 1.
cp–DNAs shown in Fig. 1 have been determined from both their mobilities relative to λ*plac*5 *Eco*RI fragments and from their length as measured by electron microscopy after gel slicing and DNA recovery. The sum of the band sizes for each electrophoretogram of the Fig. 1 is 38×10^6–45×10^6 daltons, according to the plant, the monocots giving the lowest values. Such molecular weights represent only about half the molecular weight already estimated from the contour length of the native cp–DNA molecules and from the reassociation kinetics[1,2]; monocots displaying the lowest values here also. The fluorescence intensity of the bands does not decrease steadily with decreasing molecular weight fragments. Some bands exhibit a fluorescence intensity higher than expected and it is likely that these bands are multiple. Experiments with radioactive cp–DNA are required to state the band multiplicity precisely.

The characteristic band patterns produced after *Eco*RI digestion of cp–DNA from three plants of the genus *Nicotiana* (*N. rustica* var. Pavonii, *N. tabacum* var. Samsun, *N. glauca*) are presented on Fig. 2. It is noticeable that the three patterns are very similar, although not identical. A difference involving a few bands (indicated on Fig. 2) allows the recognition of each *Nicotiana* species. Gel electrophoresis of *Eco*RI digests provides an extremely sensitive method to evidence intergenera as well as intragenus differences at the cp–DNA level.

This method should be very useful to (1) demonstrate the function of cp–DNA by illustrating the association of genetic markers with individual groups of restriction fragments; (2) confirm the nature of parasexual hybrids; (3) analyse the phylogeny within some important genera; and (4) elucidate the origin of male sterile line.

We thank Dr H. Fukuhara for a gift of *Eco*RI endonuclease and Dr Tiollais for the λ*plac*5 DNA used in these studies.

New method of detecting singlet oxygen production

SINGLET oxygen is receiving increasing attention as a reactive species in many chemical or biological reactions (see refs 1–3 for recent reviews). We report here a new method for detecting the formation of singlet oxygen by the generation of stable nitroxide radicals from sterically hindered amines.

Excited oxygen (singlet oxygen) can be produced for example, by microwave discharge in the gaseous phase[4], by chemical reactions (the first reported one being the hypochlorite–H_2O_2

reaction[5]) or by energy transfer from triplet states of sensitisers according to the following scheme[2]

$$^3\text{Sensitiser} + {}^3O_2 \rightarrow {}^1\text{Sensitiser} + {}^1O_2$$

Singlet oxygen can be identified as an intermediate in a given reaction by (1) the quenching effect of the azide ion ($k_q = 2.2 \times 10^8$ M^{-1} s^{-1} in methanol[6]); (2) the enhancing effect of deuterated solvents[7]; (3) the identity of the oxidation products of a substrate to those obtained in a reaction known to involve singlet oxygen[3].

Quenchers other than NaN_3 have also been studied. Among these, amines constitute a separate class, probably because they are highly specific for the $^1\Delta_g$ state[3]. Typically, their quenching rate constant (k_q) ranges from 10^5–10^7 M^{-1} s^{-1} (ref. 8). The quenching mechanism has not been fully elucidated, however. The existence of a charge transfer complex between the amine and the singlet oxygen molecules has been proposed; the rationale for such an hypothesis is the good correlation found between log k_q and the ionisation energy of the amines[8]. Since such complexes are reversible, the amines are usually considered as inert quenchers[3]. A fairly new class of stable free radicals, the nitroxides, are, however, commonly synthetised by oxidation of sterically hindered amines[9]. The high specificity of amines for $^1\Delta_g$ and the possibility in some particular cases of stabilising the oxidation products, led us to try a new method in which stable nitroxide radicals would be generated by reaction with singlet oxygen and would be easily detectable by electron spin resonance (ESR) spectroscopy.

In our experiments, singlet oxygen was produced either through the classical chemical reaction between H_2O_2 and NaOCl or by energy transfer, and 2,2,6,6-tetramethylpiperidin was added to the medium. A slight ESR signal was already

Fig. 1 Nitroxide concentration against duration of light exposure ▲, Proflavin; ●, toluidine blue; ×, fluorescein; △, retinal; □, xanthotoxin; ○, without sensitiser. Sensitiser concentration, 10^{-3} M; 2,2,6,6-tetramethylpiperidin concentration, 1.15×10^{-1} M; nitroxide concentration before illumination, 0.3×10^{-4} M. Light source, Osram HBO 500; filters, Schott WG 345 and KG1; total incident intensity (300–800 nm): 14×10^{15} photons cm^{-2} s^{-1} (by chemical actinometry).
Fig. 2 Nitroxide concentration against duration of light exposure in the presence of 10^{-3} M retinal. 2,2,6,6-tetramethylpiperidin concentration 1.15×10^{-1} M; nitroxide concentration before illumination, 0.3×10^{-4} M. $\square$, CD_3CD_2OD; $\bigcirc$, CH_3CH_2OH; $\bullet$, $CH_3CH_2OH + NaN_3$ (concentration, 10^{-2} M). Illumination conditions are the same as in Fig. 1. The lag period observed in deuterated ethanol can be interpreted in terms of a buildup period for singlet oxygen steady-state concentration. Inset: ESR spectra before (. . .) and after (—) illumination. Microwave power 4 mW; modulation amplitude 1 gauss; temperature 22 °C.

observed before any reaction. This spectrum characterises nitroxide free radical[10] present as an impurity in the commercial product (Aldrich); its concentration does not exceed 0.3‰.

When the chemical reaction is performed in the presence of the amine, free radical production occurs. The corresponding ESR spectrum is identical to the one observed before reaction but its intensity is greatly increased. This suggests that it is the presence of singlet oxygen which leads to nitroxide formation.

For testing the photochemical process, various sensitisers were studied. Toluidine blue and fluorescein are known to generate $^1O_2$ (refs 11 and 12). It has only been suggested that retinal and proflavin are able to do so[13,14]. On the other hand, although there are some indications[15] that furocoumarins do not react with oxygen in biological sensitisations Poppe and Grossweiner recently[16] attributed lysozyme photodynamic inactivation to singlet oxygen generated by energy transfer from xanthotoxin triplet state; this latter compound was therefore studied.

Photochemical experiments were performed mainly in ethanol. One millilitre of sensitiser solution (1 mM) was introduced into rectangular quartz cuvettes (1×1 cm) and 20 µl of amine were added. Aliquots were taken in calibrated capillaries (Drummond microcaps 50 µl) before exposure to light and after different exposure times. Samples were immediately measured with a Varian E3 ESR spectrometer.

Illumination of the different chromophores also led to nitroxide production. Their rate of formation is shown in Fig. 1. In our experimental conditions, proflavin gave rise to the steepest initial slope but underwent rapid auto-oxidation. Toluidine blue, on the other hand, gave a fairly linear yield up to a 20-min exposure. Therefore it seems to be a very good sensitiser for nitroxide photoproduction, comparable to

retinal and fluorescein, although less effective. With respect to xanthotoxin, the small but measurable yield observed seems to confirm the results reported by Poppe and Grossweiner[16].

To prove definitively that singlet oxygen is implicated, the effects of sodium azide and deuterated ethanol were studied and the results are presented in Fig. 2. In deuterated ethanol, the free radical rate formation increases more than tenfold whereas in the presence of azide, free radical production is abolished.

When experiments were carried out in nitrogen-bubbled solutions, no nitroxide formation occurred. The illumination was usually carried out in an open cell in equilibrium with the atmosphere. In those conditions, the ESR linewidths are fairly large (2.25 gauss) due to the high oxygen concentration in ethanol (6.4 mM). When experiments were performed in a sealed cell, an important linewidth reduction was observed during the photochemical reaction. This phenomenon reflects oxygen consumption within the medium.

In conclusion, a new method for detecting singlet oxygen production can be derived from the experiments reported here. The results shown in Fig. 2 indicate that the reaction is highly specific for singlet oxygen. The technique allows a specific study of free radical formation without interference from other possible side products. Moreover the method, which is convenient and easily set up, can detect free radicals at concentrations as low as 100 nM. Preliminary results performed in aqueous solutions gave similar results to those obtained in ethanol. Possible applications of the method to biological reactions have still to be explored.

Triplet state involvement in primary photochemistry of photosynthetic photosystem II

THE primary photochemical reaction of photosynthesis is widely accepted to be a one-electron transfer from a chlorophyll (or bacteriochlorophyll) species to an acceptor entity[1]. Until recently it had been assumed that the excited state precursor to the electron-transfer reaction was a singlet state in each of the photosynthetic photosystems. This view is based on the fact that estimated fluorescence lifetimes[2] of $\sim$ 7 ps at the reaction centre are much too short compared with intersystem crossing times of the order of 5 ns for chlorophyll in vitro[3]. Robinson[3] pointed out, however, that the increase in fluorescence yield observed when the photosystem II (PS II) trap is closed is far less than that expected if photochemistry, such as electron transfer, were the sole quenching process. He and others[4,5] have proposed the involvement of a triplet state in the mechanism of the photochemical electron transfer, but this

suggestion has received little attention. Blankenship *et al.*[6] reported an electron spin resonance (ESR) signal arising from photosystem I (PS I) which initially exhibited microwave emission due to chemically induced dynamic electron polarisation (CIDEP). They maintained that this observation indicated that the excited state precursor to the formation of the radical species must have been in a triplet state to account for the CIDEP phenomenon. We report here the first observation of ESR signals exhibiting the CIDEP phenomenon from free radicals associated with PS II of chloroplasts and whole algae. As discussed below, this provides additional evidence that triplet states may be involved as intermediates in the mechanism of photochemical electron transfer in photosynthesis.

In our experiments we used a Varian E12 ESR spectrometer with the addition of a flash-photolysis excitation and detection system[7], a Photochemical Research Associates Model 610 flash system with a flash half life of ~ 25 μs and a Biomation Model 610B Transient Recorder buffered into a Fabritek Model 1072 Instrument Computer. The flashes were filtered by a Corning CS2–64 red filter. We modified the response time of the ESR spectrometer so that the rise time was 50 μs using 100-kHz field modulation and have observed kinetic responses at temperatures from 10 K to 300 K in the whole algal systems.

Figure 1*a* shows a typical kinetic response for *Scenedesmus obliquus* algae grown on a 99% deuterated medium[8]. We have also obtained responses from spinach chloroplasts, but signals from the whole algae *Anacystis nidulans* and *Scenedesmus obliquus* were more intense and more reversible than signals obtained from the chloroplasts. A negative excursion in Fig. 1*a* corresponds to the microwave emission mode and a positive excursion to the microwave absorption mode of ESR. If the photochemistry of PS II is blocked, by means of several red flashes before freezing the algae in the presence of 0.1 mM hydroxylamine and 20 μM DCMU (3-(3,4-dichlorophenyl)-1,1-dimethylurea)[9], the kinetic response is greatly diminished (Fig. 1*b*). This, and further evidence given below, leads us to believe that the detected ESR signals arise from free radicals associated with PS II. The signal shown in Fig. 1*a* was reproducible from the same sample for many thousands of light flashes.

ESR spectra at a fixed time after the flash were obtained from kinetic traces taken at many magnetic field positions close to $g = 2$. It was apparent in spectra from normal algae grown on protonated media that two separate fast transients gave rise to superimposed spectra in the free electron region. Furthermore,

Fig. 1 A typical flash-induced ESR kinetic profile for fully deuterated *Scenedesmus obliquus* frozen as a thick suspension in 20 mM phosphate buffer (pH = 7.5) with 10 mM NaCl and 50% glycerol at 10 K with 0.1 mW microwave power. Collection of 128 flashes in the presence of 20 μM DCMU and 100 μM hydroxylamine: *a*, after freezing in the dark; *b*, after freezing following several red flashes at 300 K.

Fig. 2 *a*, A point-by-point magnetic field profile of the rapid transient amplitudes (×) and of the slow transient amplitudes (■) induced by flashing 256 times fully deuterated *Scenedesmus obliquus* suspended in 20 mM phosphate buffer (pH = 7.5) with 10 mM NaCl and 50% glycerol at 100 K with 1 mW microwave power and 2.5 gauss modulation amplitude at 100 kHz. The *g* factors are accurate to a precision of ±0.0003. *b*, A point-by-point field profile of the rapid transient amplitudes (×) and of transient amplitudes of Signal 1 (▲) induced by flashing 1,024 times fully deuterated *Scenedesmus obliquus* suspended in the same medium at 200 K with the same instrumental conditions and precision as in *a*.

the observed spectral line shapes for the fast transients were mixtures of absorption and dispersion signals arising, we believe, from rapid passage effects[10]. The spectra of rapid and slow transients (Fig. 2*a*) for deuterated algae, however, were found to be simpler because of less overlapping of the spectra of the separate transients as a result of the collapse of some unresolved proton hyperfine structure. Rapid passage effects are also responsible for some distortion of the line shapes in Fig. 2*a*.

Figure 2*b* shows the field profile of the fast transients for deuterated algae relative to the reversible part of P700 (signal 1) at a temperature of 200 K. It is evident that the fast transient signal is in opposite phase to that of signal 1, but nonetheless, it is readily detectable at this temperature. It is significant that the new transient is detectable at temperatures down to 10 K, where signal 1 is not significantly reversible for detection on a millisecond time scale. This behaviour implies that the reversible transient signal is independent of the primary photochemistry of PS I.

We interpret the kinetic response in Fig. 1*a* to fast and slow decay processes in opposite phase. The fast decay corresponds to electron spin lattice relaxation causing the spin populations (initially inverted) to relax to a Boltzmann distribution. The slow decay corresponds to a chemical disappearance of the radicals. On the basis of the spectra observed for the rapid transients from both protonated and deuterated algae, we can assign the two observed radical species, one with $g = 2.0042$ and another with $g = 2.0025$. The latter corresponds very well to the ESR spectrum of P680[+], the chlorophyll *a* species acting as the primary donor of PS II and the former could arise from a

plastosemiquinone anion radical. There is now good evidence for P680 being the primary electron donor[11-24] in PS II, and there is good optical evidence that a plastoquinone molecule acts as the primary acceptor[21-26], although no one to date has detected an ESR signal from the primary acceptor. The slow phase of decay of Figs 1*a* and 2*a* could correspond to an electron-transfer back reaction between the primary donor and acceptor. A decay half time of ~ 1 ms for both the donor and the acceptor is comparable with the 3-ms decay measured optically at low temperatures in chloroplasts[21-24].

Given that our interpretation of the kinetic response and ESR spectra is correct, we should explain how a population inversion of spin states might be established when the free radicals are created by the photochemical electron transfer from P680 to the primary acceptor. The phenomenon of CIDEP was first observed[27] by Fessenden and Schuler and has since been observed for many radicals formed in solution[28]. As yet, the work of Blankenship *et al.*[6] and our present work are the only reports of CIDEP from a biological solid-state system.

Two mechanisms have been proposed[28] to explain the observation of CIDEP. The first is the radical pair mechanism, but it can be excluded in the case of a solid-state system, because it requires free diffusion of radicals in a dynamic fluid state. The photochemical triplet mechanism involves an intersystem crossing into a triplet excited state with unequal rates of populating the three triplet levels. If electron transfer occurs before spin-lattice relaxation in the triplet state can restore a Boltzmann equilibrium, then both the resulting radicals should be observed with initially inverted spin populations. Clearly, the triplet mechanism can explain our results since we have a solid-state system.

If a triplet state of the P680 chlorophyll species is the precursor to photochemical electron transfer in PS II, then intersystem crossing must occur very quickly. Fluorescence decay measurements[29] indicate that fluorescence $t_\frac{1}{2}$ are no more than ~ 100 ps in PS II, which suggests that there must be some mechanism for enhancement of the intersystem crossing rate to allow for such rapid quenching of fluorescence. One possibility is that the manganese present in PS II is in close proximity to P680: transition metal ions are known to enhance intersystem crossing rates[30]. One other possibility is that P680 is a dimer of chlorophyll *a* which has a structure analogous to that of P700 in PS I. The quenching of the excited singlet state would then correspond to a charge separation within the dimer pair (P^+P^-). In such a charge-transfer state, the separation between singlet and triplet states would be small (because of the greater distance between the two unpaired electrons), and so an enhanced intersystem crossing rate would be expected.

Our results do not prove that a triplet state must be an intermediate in the photochemistry of PS II, as there may be another mechanism which could produce the CIDEP phenomenon from a single-state precursor, but they should provide impetus to a search for evidence of short lived triplet states in photosynthetic systems, using picosecond optical spectrometers.

Fluorescence lifetimes of haem proteins excited into the tryptophan absorption band with synchrotron radiation

FLUORESCENT spectra of tryptophan residues in proteins are a powerful tool in the study of the intraprotein medium, primarily as an indicator of local conformational changes of the residue microenvironment. Fluorescence quantum yields of tryptophan in the case of haem proteins, however, are very small $(Q \leq 0.002)^1$, and a dramatic increase $(Q' \sim 0.2)$ is observed after haem removal. The photodissociation of carbon monoxymyoglobin, when irradiated using ultraviolet light, has indicated the transfer of excitation from the aromatic amino acid to the haem group[2,3] following a mechanism of the Förster type[4]; this transfer has a probability[1] at least 100 times greater than the fluorescence, and therefore some 20 times greater than the other competing radiation-free processes. Consequently lifetimes have been considered to be extremely small and no attempts have therefore been made to measure them. This type of information is, however, vital for our understanding of the quenching mechanism by haem. We have therefore reinvestigated the problem with respect to decay times for ox, horse and adult human haemoglobins and their α and β subunits when excited in the tryptophan absorption band. Our data are not refined—lifetime values reported here have a rather poor precision (~ ± 0.25 ns)—but those obtained using ox, horse and human samples demonstrate similar behaviour. In some selected cases data from haemoglobin and apohaemoglobin have been compared.

Membrane-free haemoglobin samples were prepared by 22,000 r.p.m. centrifugation[5]. The haemoglobin solutions were (poly)crystallised according to Drabkin's method[6], and fresh samples were used. Haem-free haemoglobin samples were obtained from human adult haemoglobin by precipitation in acid acetone medium and then renatured as described previously[7].

Haemoglobin splitting in corresponding subunits was carried out according to Bucci's procedure[8]; thiol group regeneration, following Geraci[9]; and free SH titration in accordance with Boyer[10]. The purity and the homogeneity of α_{SH} and β_{SH} chains was controlled by electrophoretic analysis over starch gel, and by optical absorption spectroscopy. Their non-denatured character was verified by determining their capacity of association for haemoglobin reconstitution.

Ferrihaemoglobin was prepared by oxidation of deoxyhaemoglobin *in vacuo* with potassium ferricyanide in moderate (5–10%) excess (pH ~ 7), the ferricyanide surplus being eliminated by gel filtration through a G25 Sephadex column in phosphate medium.

For all samples a common solvent was used: 10^{-2} M KH_2PO_4–Na_2HPO_4 (pH = 7) buffer in sterile and clear commercial Biosedra water, presenting a weak fluorescence. The pre-existing organic phosphates (DPG) in the haemolysate have not been eliminated, their concentration in the stock solution being estimated[11] at between 0.7 and 1 equivalent per tetramer of

protein. Care was taken to avoid bacterial contamination (filtration through adequately treated 0.2-μm Millipore).

Native protein solutions (about 2.10^{-6} M, of haem or of polypeptide chain) from three different donors of each mammalian species (four in the human case) have been studied at 25 ± 0.5 °C and 3 ± 0.5 °C, always with fresh samples not older than 15 h, and stored at 4 °C in the above buffer.

Fluorescence decay times were obtained using the synchrotron radiation from the Orsay Storage Ring (ACO; for a technical description of the ACO machine, see Fourth, Fifth and Sixth int. Conf. High Energy Accel., Dubna (1963), Frascati (1965) and Cambridge, Massachusetts (1967) and ref. 12.) as a pulsed light source coupled with the Single Photoelectron Timing Method[13,14]. The ACO machine was working in the e^+, e^- collision ring mode for a high energy physics experiment with 510-MeV electron energy and 25–10-mA electron circulating current; in these 'parasitic' conditions the available light intensity is smaller by a factor of 5–10, compared with the photon flux obtained using ACO working in the Storage Ring mode, fully geared to synchrotron radiation.

Samples were excited at three different wavelengths (270, 280 and 290 nm), selected using a high flux vertical 'Lavollée-type' monochromator[15], the excitation spectral bandwidth being about 32 Å. All the emitted fluorescence with wavelength higher than 340 nm, was detected at right angles through a set of three Schott-type filters (WG 320, 330 and 345) using a RTC 56 DUVP/03 photomultiplier. Decay curves were recorded by counting signals, in the positive mode for a given time, from the excited haemoprotein solution; and then, in the negative mode, signals for an equivalent active time from the buffer solvent at the same excitation wavelength. With this latter operating mode (which is justified by the fact that synchrotron radiation is perfectly constant in shape and amplitude), and because of the small optical density of the haemoprotein solutions (see below), the stray light level from the excitation is minimised. Therefore, when verified using a MgO diffusing screen, it turns out to be less than 1%, in any case.

We will comment here only on some unexpected results (unpublished). We have roughly verified the fluorescence efficiency depletion when going from apohaemoglobins to haemoglobins, by comparing photon-counting rates in the same experimental conditions (globin counting rate $\sim 4 \times 10^4$ Hz; ferrihaemoglobin, $\sim 5 \times 10^2$ Hz, for example); lifetimes are, however, very little changed (the main component in the ferrihaemoglobin decay is only $\sim 20\%$ smaller: τ(globin) ~ 4.3 ns, τ(ferrihaemoglobin) ~ 3.5 ns, both at 3 °C. (Apohaemoprotein and haemoprotein fluorescence decay are, in most cases, non-exponential, with the main component usually the shortest one.) Because our data are not refined, we cannot find significant changes in fluorescence decays using the three excitation wavelengths mentioned above.

To eliminate the possibility that the observed emission was not due to haem losses in the haemoprotein solution[21], some samples were controlled by comparing the optical absorption in the 280-nm and 540-nm regions of their ferricyanomet derivatives. These controls have proved that the total amount of haem-free globin, if any, could not exceed 0.5%; a haem loss artefact can therefore be excluded.

An important decrease in the quantum yield, when fluorescence lifetimes are only slightly changed would indicate some sort of quenching with a strong 'static' component[16,17], the de-excitation being related to some non-fluorescent complex[18] between the fluorophore (tryptophan) and the inhibitor (haem). It may be, however, that this non-fluorescent complex is not permanent, the static quenching indicating statistical fluctuations; the oscillations of tryptophan residues (it is known that the tryptophan emission in the globin is strongly depolarised, (unpublished results)) could correlate periodically, however, with the collective movements of the macromolecules in a particular orientation, and thus escape from the influence of haem. We could then imagine that, statistically, a small fraction ($\sim 1\%$) of the total excited tryptophan population are emitting their characteristic fluorescence. The small, but significant decrease in the ferrihaemoglobin (tetramer)

decay time, compared with that of the globin (dimer), could be explained by significant changes in the tryptophan microenvironment, reflecting global conformational changes induced in the macromolecule by the presence of haem.

On the $\alpha_{SH}O_2$ chain, besides the static quenching by the haem groups, there must also be a 'dynamic' one, because of the marked decrease both in the counting rate and in the lifetime: τ(α globin) ~ 4.4 ns, τ($\alpha_{SH}O_2$) ~ 1.0 ns; both at 3 °C (ref. 16). The $\beta_{SH}O_2$ chain shows a clear non-exponential decay, the main component having a lifetime of the order of 1.4 ns at 25 °C; the other one, much weaker, is much shorter (probably of the same order of magnitude as that of the α_{SH} chain, see below). The same behaviour is found in the case of ferrohaemoglobin with an O_2 ligand; here the main component of the decay is about the same (~ 1.5 ns; always at 25 °C) but the contribution of the short component is much weaker than in the β chain. Note, however, that in the isolated α chain (monomer) there is a single tryptophan (tryp 14) residue; whereas in each subunit of the β protein (tetramer), there are two tryptophan residues (tryp 15 and 37). In addition, very little is known about the conformation of isolated α and β chains. Nevertheless there is a fundamental difference between the three haem proteins—$\alpha_{SH}O_2$, $\beta_{SH}O_2$ and HbO_2—and the ferrihaemoglobin, that is, the absence of O_2 ligand in the latter.

We have also observed that lifetimes decrease substantially when increasing the temperature from 3 to 25 °C: in the ferrihaemoglobin τ changes from ~ 3.5 ns to ~ 2.4 ns; from ~ 1.0 ns to ~ 0.5 ns, for the $\alpha_{SH}O_2$ chain. This time, in contrast with the unexpected results mentioned above, counting rates change in the same direction and in the same proportion, as would be expected. This behaviour could indicate substantial changes in the macromolecular conformation (it is known that the protein structure is very sensitive to temperature).

In addition, we must also consider a possible effect from oxygen; indeed, one could be tempted to attribute, at least partially, the dynamic quenching to oxygen diffusing into the protein[18,19]. Although the macroscopic concentration of dissolved oxygen in the aqueous samples does not change very much in our temperature range ($\sim 3.9 \times 10^{-4}$ M at 3 °C; $\sim 2.5 \times 10^{-4}$ M, at 25 °C), it is possible to imagine the presence of important local fluctuations: the intraproteic medium, covered with hydrophobic residues[20], could, in some conditions, act as an 'oxygen trap', the Henry laws being no longer valid. Another alternative hypothesis would be to consider the oxygen diffusion as being influenced by temperature-induced changes in the protein structure.

Further work will be necessary to answer some of these many questions—precise fluorescence quantum yield measurements, emission frequency distribution, time-resolved frequency distribution, and fluorescence time-dependent depolarisation.

We thank the DMA (the High Energy Physics Experiment at ACO) engineers and physicists for support, and Drs A. Tramer and L. Lindqvist for discussions.

reviews

Images of terrestial processes

Peter J. Smith

The Bowels of the Earth. By John Elder. Pp. vii+222. (Oxford University: London, 1976.) £6.00.

ACADEMIC writers have usually sought to develop as impersonal a style as possible, presumably in the belief that to do otherwise would be to impair their reputation for impartiality and objectivity or detract from the science itself. This tradition rightly persists, although at the same time there is a minor (but growing) and not entirely unwelcome movement towards the injection of 'personality' into the business. As far as the Earth sciences are concerned, the latter trend seems to have originated with Peter Wyllie (*The Dynamic Earth*, Wiley, 1971) who began in a small way by placing more overt emphasis on the scientists involved and later extended the technique with great effect in *The Way the Earth Works* (Wiley, 1976).

There is no doubt that in moderation, and performed with Wyllie's flair, an attempt to present a more sparkling view of science can be entertaining and give a more realistic picture of how science actually develops. But as Elder demonstrates here, it can also degenerate into irrelevance, absurdity and even crudity. The fact that the title of his book has achieved recognition in the new (1976) edition of *The Concise Oxford Dictionary* hardly disguises the vulgarity and gimmickry of its use in a serious context. It is not even accurate. How a word which refers metaphorically to 'innermost parts' can be taken to apply to the whole Earth from core to crust (not to mention the Earth as a body in space) is beyond imagining.

None of this would matter perhaps if it were not indicative of similar errors of judgement throughout the book, chiefly in the addiction to inane metaphor and analogy. The Earth, for example, is variously a jam-pot, a stone, a jumping bean, an egg and much else besides, presumably in the mistaken impression that these homely analogies will appeal to what in these days of sexual equality Elder chooses to call 'the man in the street'. All of which is a pity because it obscures what is at heart a fascinating conception, namely, that the Earth may be viewed as a series of dynamic processes

occurring on a wide range of scales. To adapt one of his more sensible metaphors, Elder has given us an interesting sketchbook of the Earth—a collection of interacting models and images of terrestrial processes which vary in size, content, validity and credibility in reflection of what we know and can deduce from a body which is in the last resort inaccessible.

It is an unusual, if at times idiosyncratic, gallery which could be viewed with benefit by all Earth scientists, not least the 'experts' whom Elder explicitly excludes. But whether, as he fondly imagines, it is equally accessible to the

man in the street, I take leave to doubt; such an unfortunate creature would find himself bombarded by 'rather a lot of mathematical formulae' and is unlikely to find complete consolation in the index-*cum*-glossary. Some background in science would seem to me to be prerequisite. But with that reservation, and not forgetting the irritations and imperfections, I would recommend the book as an important way of looking at the terrestrial machine. □

Peter J. Smith is a Reader in Earth Sciences at the Open University, Milton Keynes, UK.

Molecular orbital theory

The Determination and Interpretation of Molecular Wave Functions. (Cambridge Monographs in Physical Chemistry, Vol. 3.) By Erich Steiner. Pp. viii+205. (Cambridge University: Cambridge and London, July 1976.) £11.50.

THERE are so many books on molecular orbital theory that it is hard to find a gap in the literature. One unfilled need is for a book at an elementary level which will bridge the separation between theoretical and experimental chemists. In particular such a book should enable the experimentalist to use the wave function computer programs which are so freely available thanks to the Quantum Chemistry Program Exchange. This book only fulfills this need in part.

The level is elementary and reasonably up to date, but the book contains no more than is to be found in a couple of chapters of standard texts supplemented by one or two recent review articles. Only molecular orbital theory is included. Indeed the preface states that "since 1960 there has been a declining importance of the valence bond approach as a practical tool of the computational quantum chemist"; a view which would not be supported by Goddard or the Italian or Bristol schools.

The early chapters summarise standard theory in a clear and concise manner, and introduce the required notation. Further chapters are devoted to the orbital approximation and be-

yond; to the representation of the orbitals and charge densities with a final look at the chemical bond. It is hard to quarrel with the content although the form in which it is presented reflects the author's view of the subject. Others might feel that natural orbitals, for example, are of interest less in a chapter on electron distribution than in the section on correlation energy.

Within the constraints of the book one definite omission is a detailed look at open-shell methods. So much published work is restricted to closed-shell ground states of molecules, possibly because a convenient account of the problems and techniques involved when there are unpaired electrons is not to be found in most simple texts. There is no coverage of molecular properties other than charge distribution.

For experimentalists an additional chapter on how to produce data for a standard computer program would have been helpful, together with some examples of how to enter these data and interpret the output. Without this, the book should be valuable as a reference work for the conveted who run calculations but probably not sufficient to enable the practical chemist to run his own. On the other hand, armed with this book he should appreciate what the theoretician has done.

Graham Richards

Graham Richards is a lecturer in the Department of Physical Chemistry and a Fellow of Brasenose College, Oxford, UK

Access to soil ecology

The Distribution and Diversity of Soil Fauna. By John A. Wallwork. Pp. xii + 355. (Academic: London and New York, April 1976.) £11; $17.25.

IN 1970 Wallwork published his *Ecology of Soil Animals* which has since been accepted as an invaluable reference and teaching aid. With commendable frankness he introduces the new book as "something of an Adam's rib, a companion volume . . .". To anyone who has shared the development of his subject over the past thirty years, reading the new work is a most enjoyable experience for many original insights, a clear and often amusing style, and some superb illustrations. The atmosphere conveyed is almost that of a set of personal discussions, perhaps following a series of seminars, among people already familiar with the jargon and many of the ideas.

The chapters are mainly devoted to major ecosystems in turn, grasslands, moorlands, forest soils and so on. Here Wallwork encounters the organisational problem which faces all writers of ecology books: the material to be covered is related in many logical 'dimensions' but must be discussed in linear order. Many topics, common to different ecosystems must either therefore be repeated or introduced rather arbitrarily in a particular chapter. The second practice is followed—for example, discussions of pedology and feeding biology in the grassland chapter—and the problem of re-locating a particular discussion is not fully met by means of cross references. One feels the need for a diagrammatic master plan in the introduction. The excellent index, however, goes a long way to overcome this difficulty.

The chapter on "agricultural practice and the soil fauna" is a short but valuable introduction to the literature of a fast-expanding field; and the final chapter faces the perennial problem of how so diverse a fauna persists in an apparently rather uniform and narrow spatial zone. Throughout, the discussion is immensely strengthened by Wallwork's experience of soils from all parts of the world.

This is hardly, as claimed on the book jacket, "a basic introduction to the subject for students unfamiliar with the soil fauna". Many terms and ideas are either used without definition or are only defined after first introduction (the vocabulary of saprophage, fungivore, and so on, and the terms 'stentotopic' as against 'eurytopic'). These are perhaps further indications of the true readership of the book: it is probably best thought of as a synthesis, a companion volume and extension of *The Ecology of Soil Animals* and a valuable means of access to the literature of soil ecology.

Somatic chromosomes

Chromosomes in Mitosis and Interphase. (Handbuch der Mikroskopischen Anatomie des Menschen.) By Hans George Schwarzacher. Pp. viii + 182. (Springer: Berlin and New York, 1976.) DM 136; $55.80.

THIS monograph is essentially concerned with the structure and organisation of the somatic chromosomes of man and I must say at once that I enjoyed reading it. Schwarzacher's excuse for writing such a book is the veritable flood of new information on human chromosomes that has been unleashed following the development and application of a wide variety of new techniques over the past few years.

The information and discussion is parcelled into ten chapters beginning with simple accounts of chromosome morphology, nomenclature and the human karyotype. There is a good review of what little we know of chromosome structure in the interphase nucleus as revealed by histochemical and electron microscope studies, supplemented by the observations on prematurely condensed chromosomes obtained by the method of Rao and Johnston using the cell fusion technique. Heterochromatin and chromosome fine structure, as studied by electron microscopy, are considered in detail, as are the main techniques utilised to produce the various banding patterns in human chromosomes. The two chapters on chromosome banding and fine structure are particularly

⬤ *Climate and the Environment* by J. F. Griffiths (UK edition by Paul Elek reviewed in *Nature*, **262**, August 5, 523, 1976) is also published in the USA by Westview Press, Boulder, Colorado 80301. Price : $12.75.

good, and present a clear account of the facts and the various interpretations and speculations on mechanisms and structure. In such a rapidly developing field it is inevitable that some parts of the text are a little out of date—for example, some of the more recent work on human satellite DNAs is not discussed, but this is not a major criticism.

Geneticists who have not been following closely the human cytogenetic scene should be impressed by a wealth of chromosome polymorphisms that have been unearthed in the chromosome complements of various human populations using modern cytological techniques, and these are admirably summarised by the author. Man's chromosomes are varied indeed and, for example, our own studies in Edinburgh reveal that some 3% of the local population have inversions involving the whole or part of the C band on chromosome 1; that all of us are heteromorphic for one or more C- or Q-band regions; and that the chromosome phenotype of an individual may be almost as distinctive as his fingerprints! Schwarzacher, in fact, points out that an analysis of chromosome polymorphisms would give successful paternity exclusion tests in about 75% or more of cases.

The text of the book is very clearly written; it is well illustrated and easy to read with only rare glimpses of minor problems of translation from the German, as in sentences such as "With this term the morphologic separation of complete chromosome sets of genomes is meant."

The general style tends to be rather more descriptive than discursive and I personally would have preferred more discussion of some of the interesting points brought out by the author. For example, a photograph and two lines of text impart the information—substantiated by all workers interested in chromosome replication—that daughter strands are always placed to the outside of parental templates. This implies a certain pattern of DNA segregation which must of itself reflect on organisation of chromosome structure—something that is not really considered in the book.

This little book is timely, and shows that we have come quite a long way in the past five years or so towards revealing the enormous diversity and variation in structure of man's chromosomes, but we have a long way yet to travel before we can really understand what these variations mean both in terms of chromosome organisation and in possible consequences to the individual. Swarzacher's summary sets a very useful background and is to be highly recommended to those who are already journeying in this field or who are about to start on their travels.

H. John Evans

Professor Evans is Director of the Medical Research Council Clinical and Population Cytogenetics Unit, Western General Hospital, Edinburgh, UK.

obituary

Dr A. P. Rowe, the wartime Head of the Telecommunications Research Establishment—the home of radar—died at Malvern in May 1976 at the age of 78.

Albert Percival Rowe trained as a meteorologist and worked in the Air Ministry's Laboratory in Imperial College after the 1914–18 War. From there he became Personal Assistant to H. E. Wimperis, the first Director of Scientific Research at the Air Ministry; and in June 1934—alarmed by the inadequacy of air defence in Britain, as he related in his book *One Story of Radar* (1948)—he warned the Air Ministry that "Unless science evolved some new method of aiding air defence, we were likely to lose the next war if it started within ten years". In the following November, Wimperis proposed the formation of a Committee for the Scientific Survey of Air Defence, which quickly took shape as the famous Tizard Committee.

The story has been told many times of how the principle of radar was outlined by Watson-Watt to the Committee at its first meeting, as a result of a query about death rays put to him by Wimperis, and how the independent approach of F. A. Lindemann and Churchill led to intense friction. Rowe's part in these events was to be the first Secretary of the Tizard Committee, and to decide with Wimperis to buy Bawdsey Manor, just north of Felixstowe, to house the research and development work that would be needed before radar could be made operational. In the spring of 1938 Rowe succeeded Watson-Watt as Superintendent of what was then known as the Air Ministry Research Establishment, Bawdsey, and he remained Superintendent, later Chief Superintendent, of this Establishment and its successors until the end of the war, by which time it was the great Telecommunications Research Establishment at Malvern with a staff of 3,000.

The basic notion of radar came from a Government establishment, the Radio Research Station of the National Physical Laboratory, staffed by men who—with Rowe—had gone into Government service between the wars rather than into universities. Great though the contributions of the latter were subsequently to be, they would mainly have come too late for the Battle of Britain, and it was our national good fortune that there was enough talent in Government service to

enable us to prepare for that critical phase. Recruiting from the universities had started in 1935, with men such as E. G. Bowen, R. Hanbury Brown, and A. G. Touch; and it was these recruits who, together with Watson-Watt's original nucleus of L. H. Bainbridge Bell and A. F. Wilkins, did the essential early work. Academic reluctance to work on military projects was dispelled by the Anschluss of 1938, and by the outbreak of war there was a flood of willing — and distinguished — scientific recruits, most of whom went into radar.

Rowe therefore found himself at the head of a great body of talent, from which ideas and inventions flowed throughout the war. Somehow he had to guide his establishment of scientists and engineers, few of them accustomed to Service or Civil Service procedures, into effective relationships both with the Royal Air Force and with industry. Throughout the war he held vigorously the belief that the work his Establishment was doing was vital; and at the end of it he wrote "We believe that without radar Fighter Command and the 'famous few' would have lost the Battle of Britain. We believed that without radar the night attacks by enemy bombers would have devastated our industries. We believed that without radar the work and gallantry of Bomber Command would have been largely wasted; and we believed that without radar the sea-war would have been lost and that there would have been no invasion of Europe". Although by 1948 he had begun to wonder whether this 'overwhelming belief' had been entirely justified, it had been his guiding star throughout the war and he would declare it to his staff and outsiders alike.

He was completely sincere, and it was his sincerity that enabled him to keep control of what could easily have been a very unruly Establishment. Sometimes this same sincerity led him into slightly bizarre situations : on one occasion during the war he sent a circular letter to the wives of his staff telling them that their husbands were doing work of the utmost national importance but that, unlike the serving officers with whom they were working, they were entitled only to ordinary civilian rations. Since there were various deficiencies in wartime food, it was essential that each wife should do her best to supplement her husband's diet, notably in respect of vitamins and

vitamin B in particular. This vitamin was to be had in abundance in 'Bemax' and so would she please feed this to her husband every morning. In a similar vein he had issued a station instruction at Bawdsey pointing out that the dispersal of the several research teams in huts hundreds of yards apart inhibited communication and the cross-fertilisation of ideas: he therefore urged all members of the staff to buy second-hand bicycles, and added the address of a cycle dealer in Felixstowe whom he had ascertained to have an adequate supply. But despite the comic effect produced by such instructions, he was obviously so genuine that he kept the respect, which with the years developed into affection, of his staff.

Perhaps his greatest individual contribution was the 'Sunday Soviet' held weekly in his room which, after the move of TRE to Malvern College, was of course the Headmaster's Study. Sundays were convenient for such men as Lord Cherwell, Sir Robert Renwick, and senior serving officers to visit Malvern, and Rowe would gather members of his staff for a free-for-all discussion which would last from morning well into the afternoon. Bernard Lovell, then one of Rowe's men, has recorded that "A Commander-in-Chief once complained in Rowe's office that the most lowly assistant in the Establishment would not turn a screw unless he could be acquainted with the latest strategic situation in the Middle East". The interplay between scientists and serving officers had not been started by Rowe; from their experiences in the 1914–18 War, Lindemann and Tizard, for all their differences, were united in the importance of this interplay, but it reached one of its highest expressions in Rowe's Soviets. These meetings were one of the main factors in the ultimate superiority of British radar over its counterpart in Germany, where scientists and military men were not nearly in such effective contact.

The successes of TRE were many. As regards actual inventiveness, the ideas of course originated with individuals, to whom full credit should be given; and the characteristic problems associated with getting individuals to work in a corporate body are probably less in war than in peace, where the importance and urgency of a common aim are less clear. But, even so, with all the brilliance of individuals and the corporate spirit engendered by national emergency, TRE would have been far

less effective if it had not been so well guided, and this was Rowe's contribution. He would certainly have been blamed had TRE failed, and in its success he deserved a greater honour than the CBE that was awarded to him in 1942. In fact, the whole of the radar effort was miserably recognised during the war: the Americans, who were glad to have a contingent at TRE, gave Rowe a more fitting recognition—the Medal for Merit, their highest civilian decoration, awarded directly by the President.

Writing to me in 1974 of such matters he said "I have never written of those things to anyone till now. I feel strongly about two lines of a prayer, 'To toil and not to seek for rest, To labour and not to seek for any reward'. Certainly I never thought of it during the war, when vast numbers were giving their lives".

After the war, Rowe first became the Deputy Controller of Research and Development at the Admiralty, and then in 1947 went to Australia as Chairman of the Defence Advisory Committee and Defence Scientific Adviser to the Australian Government, and in 1948 he became Vice-Chancellor of the University of Adelaide. This experience was not a happy one, as Rowe himself related in his book *If*

the Gown Fits (1960). Clearly he found the university a far less ready body to accept his guidance than TRE had been. He thought that universities should be more down-to-earth than they were in meeting the needs of the average rather than the brightest student; but, almost paradoxically, he concluded "It is necessary to replace fearfulness by courage, departmentalism by unity of purpose, egalitarianism by a measure of authority, and to recognise excellence wherever it rears its noble head". And if Australian universities are now better than they were thirty years ago, part of the change may be due to the unpopular stand that he took.

Rowe had never been afraid of expressing an unpopular view, but he felt the unpopularity all the same, when it led to loneliness as in Australia. It was here that he valued especially the support of his wife, Mary, whom he married in 1932: "Far from family and friends" he wrote in *If the Gown Fits,* "she unfalteringly supported me in my years of unaccustomed loneliness".

He came back to Malvern in 1958 and spent some of his later years teaching astronomy to the boys of the College. But—such is the way that a nation sometimes treats its faithful servants—he found it so difficult to live

on his pension that he actually left Malvern again for Malta, where the cost of living was lower. We were glad to see him back again when conditions in Malta proved not to be what he had hoped for. He had the idea of writing a further book, on invention in war, but he found the work too much and handed his papers over to Guy Hartcup, who produced the book as *The Challenge of War* (1970).

When in 1974 the Royal Society organised a Symposium on *The Effects of the Two World Wars on the Development and Organisation of Science in the United Kingdom,* Rowe was unable to attend. The meeting had the atmosphere of a reunion, and it spontaneously sent him a telegram of tribute signed by many of his wartime colleagues headed by the President, Alan Hodgkin, who as a member of TRE himself had made the first flight with airborne centimetric radar in 1941.

His final tribute came on June 18, 1976, when as many of his former colleagues as possible gathered in Malvern Priory for his Memorial Service and to recall his vital contribution as the head of what J. A. Ratcliffe in his Oration fairly described as "one of the most successful research establishments of all time".

R. V. Jones

announcements

Appointments

Dr B. J. Mason as President of the Institute of Physics, and **Dr G. H. Stafford** as Vice-President.

Awards

The Royal Society has given the S. G. Brown Award and Medal to **Frank Mackley,** a Director and Chief Engineer of J. T. Mackley & Co. Ltd, for his work on the development of the Hover Platform.
The John Scott Award for 1976 has been made to **Professor Cyril A. Clarke** and **Drs Vincent J. Freda, John G. Gorman** and **William Pollack** for their work on the prevention of Rhesus Haemolytic Disease.

Meetings

October 29, **Hybrids in Botany, Horticulture and Agriculture,** Leicester (Dr C. A. Stace, Botanical Laboratories, The University, Leicester LE1 7RH, UK).
November 15–18, **Weeds,** Brighton, Sussex (Mr W. F. P. Bishop, Frank Bishop (Conference Planners Ltd), 74

Person to Person

A survey is being initiated into the distribution and types of symbiotic *Chlorella* sp. in Britain. Information is needed on precise locations of natural habitats of green Hydra, *Paramecium bursaria, Stentor,* Sponges and other invertebrates definitely containing *Chlorella.* Please write to D. C. Smith, Department of Botany, The University, Bristol BS8 1UG.

Professor and wife wish to find small, furnished flat in S. Kensington or Belgravia, Dec. 15–30, 1976. Will exchange fully furnished 3-bedroomed house in Georgetown, Washington, D.C., Dec. 14—Jan. 6. Address replies and enquiries to D. N. Robinson, 1237 37th Street, N.W., Washington, D.C. 20007.

London Road, Croydon CR0 2TB).
November 24, **Whole Body Counting and Scanning,** London (The General Secretary, British Institute of Radiology, 32 Welbeck Street, London W1M 7PG).
December 12–17, **Automated Cytology,** Pensacola, Florida (Paul F. Mullaney, Chairman, Fifth Engineering Foundation Conference on Automated Cytology, PO Box 208, Los Alamos, New Mexico 87544).
April 14–15, 1977, **Easter Meeting of the Society for the Bibliography of Natural History,** London (Meetings Secretary, Mrs J. A. Diment, Palaeontology Library, British Museum (Natural History), Cromwell Road, London SW7 5BD).
April 18–20, 1977, **Stem Cells and Tissue Homeostasis,** Manchester (Dr R. J. Cole, School of Biological Sciences, University of Sussex, Falmer, Brighton BN1 9QG).
May 9–11, 1977, **Biosystematics in Agriculture,** Beltsville, Maryland (Dr James A. Duke, Publicity Committee, BARC Symposium II, Plant Taxonomy Laboratory, Room 117, Building 001, BARC West, USDA, Beltsville, Maryland 20705).

A place for science in the power game

As a highly respected scientific pressure group, Pugwash might reasonably have expected some publicity for the meeting it organised in London last week to discuss the fast breeder reactor. The advent of fast reactor technology is already becoming acknowledged as perhaps the major social issue of the decade in the developed world. In Britain, the Royal Commission on Environmental Pollution (RCEP) had placed the controversy firmly in the public spotlight with the publication of its report on nuclear power only six days before the Pugwash meeting. But Pugwash went unmentioned by the media. The meeting was ignored by the television corporations, passed unreported on the radio, and received not a single column inch in any of the national daily newspapers. It is worth considering why.

To some extent the unbroken media silence must be attributable to the very timeliness of the meeting, coming as it did so hard on the heels of the RCEP report. There is little press copy to be had from issues already extensively covered less than a week before. Admittedly, the meeting covered most of the contentious ground, and presented both sides of the argument. But it is worth considering whether the media's disregard might reflect more than just a fickle boredom with recurring issues. It could, for instance, say something about the rôle of Pugwash in the widening debate on the fast breeder. The part that it played in educating both scientists and politicians on nuclear matters during the 1960s stands as solid testimony to its influence at that time. But does it wield such influence still?

Pugwash itself apparently believes that it can still reach politicians by going through the back door. Last week's invitation list did not include the UK Energy Secretary, Anthony Wedgwood Benn, or his two political advisers. As for the House of Commons Select Committee on Science and Technology, members were invited, but it looked very much as though most, if not all, of the invitations were treated with disdain. Moreover, of the top personnel from the Department of Energy (DEN) only Walter Marshall could be seen, and his silence and early departure gave no clue as to whether he attended as Chief Scientist at the DEN, Deputy Chairman of the UK Atomic Energy Authority, or simply to assess any new opposition in the nuclear power game. Whatever his motives, the 350 or so scientists who confronted him offered little new beyond the contention that a target date of 1995 for a demonstration commercial fusion reactor in Europe could become realistic with more funding.

But in seeking to understand the lack of media interest not all of the blame can be apportioned to Pugwash and absent politicians. Many of the scientists present would do well to reflect what their true contribution to the fast breeder debate has been. For while it was encouraging to note the number of well-known and respected members of the scientific community eager to discuss all the implication of fast reactor technology, and even prepared to talk seriously in the corridors of the untapped potential of alternative technologies, there remain far too many who see fast breeder reactors simply in terms of load factors, breeding ratios, doubling times, and the like. Consequently, it was left to the eloquent rhetoric of a former Minister of Fuel and Power, Philip Noel-Baker, to set the debate squarely in its political and social perspective, and by the time of his closing speech many of those who ought to have been listening had seen their fill of graphs and tables and dispersed to their buses and trains.

Such a cold approach by the science community makes a mockery of the frequent protests, voiced as loudly as ever during last week's meeting, against media misrepresentation of major science-based issues. For those members of the press whom Pugwash bothered to invite, the choice was simple and clear: they could either search for sensational angles, or settle for reporting a mundane and sometimes technically bewildering meeting exactly as it happened. Evidently, they responsibly chose to do the latter and ran up against their colleagues' more newsworthy competition. Which leaves science with a sad alternative: sensational media coverage (remember the Williams report on genetic engineering?), or no media coverage at all.

And that is the crunch. For though it has wide and inescapable political and social ramifications, the debate over the fast breeder reactor is firmly rooted in science, and it surely falls on the science community to ensure that the public and their politicians are kept intelligibly informed by an impartial, well-briefed press. Sir Brian Flowers, former Chairman of the RCEP and a board member of the UKAEA, recently stressed how the rules of technological advance have changed in the developed world: it is no longer sufficient for each new step forward to be technologically realisable unless it is also socially acceptable. It is in assessing that social acceptability that science must assume a crucial rôle.

Only three weeks ago it looked very much as though the powerful British nuclear lobby might, rightly or wrongly, force an early decision in favour of the UK's first demonstration commercial fast breeder, CFR-1. Now the RCEP, in giving the reactor only qualified approval in its new report, has won a delay of a few months at least for nuclear power critics. Mr Benn and the nuclear lobby have been pushed against the baseline, and the ball has fallen to those in the other court. For the rest of the match it is the scientific community that should act as umpire. And from that position it must ensure that whoever comes out on top, every single blade of grass is covered. □

Small isn't beautiful either

AT the beginning of January 1976, one pound sterling would buy 2.02 US dollars. Last week you could get only $1.66 for a pound; at one stage as little as $1.63. This depreciation of nearly 20% in sterling is making for grim news almost everywhere in Britain; the laboratories of British universities will feel the pinch, for the Science Research Council (SRC) is almost certainly facing an acute financial crisis.

Within the past year the SRC, in common with many organisations dispensing government money, has had to accept cash limits on its activities, that is to say, it has been given a firm sum of money above which it may not commit itself. The SRC has also, of course, been told by the Advisory Board of Research Councils (ABRC) to trim its spending over the next five years by 10% in real terms. To achieve this, the so-called big sciences have been told that many major national projects cannot go ahead, and international facilities such as CERN, Institut Laue-Langevin and the European Space Agency have accordingly increased in importance. Subscriptions to these international organisations amount to about 30% of SRC's budget, and go up every time the pound goes down.

So now, in order to fulfil its international obligations, the SRC is looking for £6 million more than it had budgeted for—with cash limits in operation to prevent it from simply going to the Treasury and asking for the difference. In fact the Treasury is prepared to sympathise to the tune of £2 million, so the SRC is left either to cut £4 million off domestic expenditure, to sweet-talk CERN into letting us pay less, or (the most likely) some combination of these two.

What can be done on the domestic scene? The SRC has relatively few options open, in that much of its money is committed for long-term projects already half-done. Vulnerable spots are therefore new grant proposals and new research studentships. The new crop of research students is barely large enough to satisfy demand; even some candidates with first-class degrees have not yet been placed, and eight hundred candidates with upper-second degrees are going to be disappointed. On the research grants side the scene is even grimmer. At the last round of grant-giving there were significant numbers of applicants who failed even

though their application had been rated in the top category. This had never happened before. One of the options that the SRC is bound to be considering is that the next round of proposals (there are three a year) is simply dropped altogether.

In the somewhat longer run, SRC may have to get down to the serious business of making some of its own staff redundant. It employs nearly 3,000 in six laboratories and headquarters. With generous redundancy terms to meet, the council is unlikely to benefit in the short term from such action, but it might be encouraged by the contents of a forthcoming Confederation of British Industry document 'The Road to Recovery' which, according to *The Economist*, will suggest that industry could create a million new jobs, into which a hundred well-qualified SRC employees could surely fit.

The irony of the SRC's present crisis is that if grant giving is seriously curtailed it will be the 'small sciences' which will suffer, in order to keep the big sciences going—hardly ABRC's intention when it looked to more use of international facilities by Britain's big scientists. □

More on Argentina

CONCERN about the plight of scientists in Argentina has grown steadily since we published a letter from Italian academics on the subject (July 22). It has become increasingly clear that a country whose scientific skills have been widely acknowledged and respected is in the greatest danger of abandoning its intellectual traditions and becoming a scientific backwater. The number of academics and workers in research institutes who have lost their jobs is growing all the time, and some fairly detailed documentation is emerging.

Inevitably, when left- and right-wing extremists are at loggerheads, some of those dismissed or detained will have had a history of political activity, and thus will be vulnerable to charges of using their position for political rather than academic purposes. But many others, relatively apolitical, seem to have been caught in the crossfire. When military politicians such as General Vilas can say that "until we can cleanse the teaching area, and professors are all of Christian thought and ideology we will not achieve the triumph we seek in our struggle against the revolutionary left", there is little hope that anything resembling academic freedom can survive.

Even the Atomic Energy Commission does not seem to have escaped the general purge. At least eight employees are known to have been arrested: Carlos Calle, Dr Domi and his wife Maria Dipace, Pedro Landeyro, Antonio Misetich (who worked for a time at MIT's National Magnet Laboratory), Santiago Morazzo, Pedro Victoria. We know a little about their situation because Dr Virgilo Victoria-Troncoso, brother of Maximo Pedro Victoria and an ophthalmologist at the University of Ghent, Belgium, has recently been to see his brother (who has worked overseas, for example at Lawrence Radiation Laboratory) in prison in Argentina. He reports that the scientists, physicians and psychiatrists he saw in the Villa Devoto prison in Buenos Aires were kept in 35 cells, five to a one-bedded cell with dimensions 3m by 2.40m. They have been without meat for months. They have no legal representation, no charges have been brought against them and it is impossible to bring a writ of *habeas corpus*. "My brother", says Dr Troncosco, "has been beaten up and he has lost teeth. The situation is worse than in a novel of Kafka".

It is difficult to see why nuclear scientists have been imprisoned except

that there was a technical difference of opinion some time ago in which Dr Victoria, amongst others, was involved. It concerned the choice of fuel for a new reactor, and Dr Victoria and colleagues favoured natural uranium whereas a group of military scientists favoured enriched uranium. The former view prevailed and it may be that the military, which has in large part taken over leading civilian positions, is determined to settle an old score.

What can scientists do in the face of the widespread breakdown of all the conventional respect for the intellectual life and academic freedom? Amnesty International (53 Theobalds Rd, London WC1) can provide extensive lists of missing Argentinian academics who could be written to—preferably in Spanish, because the authorities are unlikely to pass on anything in English. Dr Victoria's address, for instance, is now 649, Unidad 2, Sierra Chica, Province of Buenos Aires, Argentina. A letter to Excelentisimo General Jorge Rafael Videla, Presidente de la Republica Argentina, Casa Rosada, Buenos Aires, Argentina couldn't do much harm. And maybe it is going to be necessary to try and find academic places outside Argentina for these victims of extremist politics. □

Watershed for poisons

Colin Norman reports from Washington on US efforts
to legislate on the controversial matter of toxic substances

A FEW years ago, a group of industrial chemicals called polychlorinated biphenyls (PCBs) were enjoying spectacular commercial success, finding their way into a vast assortment of products ranging from electrical transformers to copying paper and food packaging. In fact, PCBs are so ubiquitous, and so indestructible, that virtually everybody living in an industrialised country now has detectable levels of the chemicals in his or her tissue. They are even turning up in human breast milk, they are present in the flesh of fish from many lakes and rivers, and they have been found in the bodies of animals from such remote places as Greenland. A number of studies have shown that, when fed in relatively large amounts to animals, they may cause cancer, reproductive disorders, metabolic abnormalities, hair loss, skin eruptions, and other health problems.

Use of these versatile substances has now been curtailed in the United States. After five years of trying, the US Congress has finally passed landmark legislation requiring many manufactured chemicals to be screened and tested for toxic effects before being marketed. The grim saga of how PCBs became widespread environmental contaminants long before their health hazards were fully known is, unfortunately, far from unique. Other well-known cases include vinyl chloride, asbestos, bis(chloromethyl) ether, carbon tetrachloride and so on. And, though such occurrences are far from new (one novel theory even suggests that the decline of the Roman Empire may have been caused, in part, by lead poisoning from cooking utensils and wine vessels), they seem to be growing more numerous.

It is not surprising that there are such frequent outbreaks of panic about the toxic effects of widely used chemicals. Civilised man is surrounded by thousands of synthetic chemicals, few of which have been screened for toxic effects, and even fewer have been exhaustively tested. According to an estimate published last year by the Manufacturing Chemists' Association, for example, some 6,500 new chemical products reach the market each year. Yet only about 3,000 chemicals have even been tested for cancer-causing properties, in spite of widely accepted estimates that between 60 and 90% of human cancer is caused by environmental factors.

In short, until now, chemicals have generally been accorded the same legal rights as people—they are assumed innocent until proven guilty. But last week, after years of argument, Congress took a significant step toward writing a new bill of rights for manufactured chemicals. It passed legislation, known as the Toxic Substances Control Act, which gives the Environmental Protection Agency (EPA) broad authority to require pre-market testing of some compounds, and the power to seek a court order to keep potentially hazardous chemicals off the market.

The bill is a landmark piece of legislation for which environmentalists, some trades unions and health scientists have long fought. For the first time, it gives the federal government the power, in theory, to keep an eye on all manufactured chemicals, and it provides at least a coarse filter to screen out potentially troublesome compounds before they do much damage. In the colourful words of Senator Warren Magnuson, a key supporter of the bill, it will "no longer allow the public or the environment to be used as a testing ground for the safety of these products".

Five years of effort

It took five years of intense argument in Congressional committee rooms and behind the scenes to get any toxic substances legislation passed at all. The bill's genesis was a 1971 report by the Council on Environmental Quality, which noted that although some classes of chemicals (such as pesticides, drugs and food additives) are regulated by individual laws, there is no federal authority to control the thousands of other compounds which flood the market each year. A year later, the Senate and the House both passed toxic substances bills, but they were markedly different, and intense lobbying by industry and by the Nixon Administration prevented a final version being passed. The same thing happened in 1973 and 1974, and until very recently it looked as though Congress would again fail to reach agreement on the legislation. The deadlock was broken during what one participant described last week as "three intense bargaining sessions" between Senators and House members.

What emerged was consequently very much a compromise measure, a fact which is reflected in comments last week from spokesmen for groups on both sides of the fence. "We support the bill as a workable compromise", says Linda Billings, a Sierra Club lobbyist who has been following the legislation throughout its tortuous journey through Congress. She noted, however, that it contains a number of weaknesses and loopholes which will keep many corporate lawyers busy. Similarly, a spokesman for the Manufacturing Chemists' Association (MCA), the industry's lobbying arm, said that the bill, "while tough", is acceptable to the industry. He added, though, "I wouldn't say that we are real happy with everything that's in the bill". Spokesmen for some trades union organisations have also expressed satisfaction that a bill has finally been passed.

One lingering doubt, however, is whether or not President Ford finds the bill to his liking. Throughout the Congressional fight on the legislation, the Administration has lobbied against the measure, arguing that it would be expensive and would constitute too much government regulation of private industry (a theme frequently sounded in Ford's campaign rhetoric). But, since the bill now has broad support, and since a Presidential veto would give Jimmy Carter a gilt-edged campaign issue to exploit, Ford is expected to sign the legislation.

A key feature of the bill—which Ms Billings describes as a "watershed"—is a requirement that EPA must be informed at least 90 days before any new chemical compound is placed on the market, or an existing compound is sold for a new use. (The bill specifically exempts chemicals produced in small amounts for research purposes, it should be noted.) The manufacturer must also send along whatever information he has on the toxicity of the compound, the amount to be manufactured, the likely human exposure, and so on.

Then, if the EPA Administrator decides that the compound is likely to pose a hazard to the environment or to human health, or if he finds that there is insufficient information to judge the hazards, he can issue an order restricting or banning sale of the compound, at least until the required test data is available.

Sticking point

The EPA Administrator is clearly given very flexible authority to determine which compounds should be exhaustively tested, and which should be let through the filter. That aspect of the bill has been the chief sticking point which has held up final agreement in Congress for the past five years. The deadlock was broken by writing into the bill a provision requiring that the Administrator's decisions

must be reviewed by the courts if a manufacturer feels he has been unfairly treated. In short, if a manufacturer objects to an EPA ruling, the agency must seek a court injunction to put the ruling into effect. If EPA doesn't go to court, the ruling would be nullified.

Although that provision may seem like a huge loophole through which smart corporate lawyers can emasculate the legislation, many observers feel that in fact it will be relatively easy for the EPA to obtain an injunction. All that would be required, according to the bill, is a showing that the compound "may present an unreasonable risk of injury to health or the environment", or that it "may reasonably be anticipated to enter the environment in substantial quantities", or that there has been insufficient testing for the hazards to be "reasonably determined or predicted".

Thus, the wording is so general that EPA should have a fairly easy time in proving its case, a fact which made the provision acceptable to environmentalists. "We don't like it", Ms Billings said last week, "but we recognise that it is the best we could get". Similarly, the chemical industry sees some merit in the provision. James Hanes, chief counsel for Dow Chemicals, who has been one of the most outspoken opponents of the bill, told *Nature* that the idea "at least gives the industry the chance to contest the decision out in the open", though he noted that "I don't really see the courts requiring an overwhelming burden of proof here".

If EPA obtains its injunction, it can then specify what tests it requires, and the industry would then be in the position of having to prove that a product is safe before placing it on the market.

Priorities committee
As far as existing chemicals are concerned, the bill requires the setting up of an inter-agency committee charged with the task of drawing up a list of chemicals whose toxicity is open to question. The committee will assign priorities to chemicals and, within 12 months, the EPA Administrator is required either to issue orders for testing the top 50 compounds, or to explain why he feels testing isn't necessary.

The bill will clearly place a huge burden on EPA, which is required to go through masses of data on thousands of chemicals, decide which need testing and which should be allowed on the market, go to court to obtain injunctions, and exercise considerable judgment on what actions are necessary. Therein lies the bill's greatest potential weakness, according to many observers.

To carry out this Act, the bill authorises expenditures of only $10 million this year, rising to $12.6 million next year and $16 million the year after. Those figures should be compared with the $125 million which EPA was budgeted to enforce the Clean Air Act, or the $200 million a year budget of the Food and Drug Administration. It is difficult to see how EPA can effectively enforce the Toxic Substances Act with such small resources, and some observers have suggested that the upshot will be that EPA will be forced to concentrate on a few chemicals and allow many to slip through the net.

Monetary matters have also been a major source of concern to the chemical industry throughout the long Congressional fight over the bill, though for different reasons. There have been numerous studies of what the bill may cost the industry in terms of testing facilities, legal costs and administrative requirements. Large-scale animal tests are very expensive to conduct—according to estimates given in testimony before a House committee by officials from DuPont, for example, a complete battery of tests can cost up to $500,0000. Such figures have thus led to arguments that the bill will stifle the development of important chemicals which may only have a short production run. Some of that concern has, however, been reduced by the provision exempting research chemicals from the bill.

Assessing the cost
As for the total impact of the bill on the industry, Dow Chemicals has so far come up with the highest figure, estimating that the legislation will cost chemical manufacturers up to $2,000 million a year. The MCA thought that the cost would probably lie between $360 million and $1,300 million, while EPA suggested that it would only be about $80–140 million.

Whatever the cost may turn out to be, it will be relatively small compared with the massive total sales volume of the industry, or with the costs of treating cancers and other diseases related to environmental factors. The large cost of animal tests, moreover, should provide a strong incentive for industry to develop accurate, short-term *in vitro* tests, such as the system developed by Dr Bruce Ames at the University of California. Already, many large firms are looking closely at such systems, and are using them as rapid screening devices, essentially to develop priorities for animal tests.

It now remains to be seen whether or not President Ford will sign the bill. If he refuses, he not only runs the risk of the matter developing into a campaign issue, he would also probably do the chemical industry more harm than good. This bill swept through the Congress with support from both Democrats and Republicans, there is certainly strong public pressure for such legislation—especially since the panics over PCBs, vinyl chloride and so on—and the polls now indicate that the Democratic majority in the Congress will be much stronger next year. All those considerations suggest that an even tougher bill would emerge from the next Congress if this bill expires. That is one reason why the chemical industry has decided to give this bill at least its lukewarm support.   □

USA

Science Court on guard

A number of prominent scientists and government officials met last month to discuss a proposal to establish a 'Science Court' in the United States, to examine complex scientific issues which have a bearing on public policy. The proposal (see box) has recently been receiving considerable publicity in the United States. Wil Lepkowski reports from Leesburg, Virginia

AT first blush, the idea of a Science Court sounds a bit intriguing if not a mite exciting: a forum of distinguished scientists and engineers gathered together in court for sifting, filtering, and distilling contradictory facts into one sparkling supernatant of truth. The world of political decision-making is so messy, proponents of the science court assert, that officials would welcome a little plain, unvarnished truth from a forum that has no political stake in public issues.

This is a fairly accurate, if not precise, description of the idea behind the science court, which is mainly the invention of Dr Arthur Kantrowitz, president of the Avco Research Laboratories. For about a decade, Dr Kantrowitz has been tirelessly giving on and off the cuff speeches on the need to establish such a court and, after a good deal of effort, he finally succeeded in securing government support for a colloquim on the subject. It was held last month at the Xerox Cor-

poration Training Center in Leesburg, Virginia.

About 300 people came, representing law, science, engineering, industrial management, government administration, social science, and general subjects. No one from the humanities was observable, unless one counts anthropologist-oracle Margaret Mead. Dr Mead was the sole bearer of mirth into what was otherwise a dull, juridical gathering. She was in general kind, affirmative, but at one point called the affair a publicity meeting. That may be unkind to Dr Kantrowitz, who in sincerity is outranked by no one. But the whisperings around Washington in that small circle called the science policy community (not to be confused with the working scientists) is to give Kantrowitz his day and let the whole idea collapse under its own unworkable pretensions.

Nothing was really decided at the colloquium. Individuals theorised how it might work, what might be the snags, how the right panels of experts would be picked according to the issue under debate, who would choose the experts, how information would pass between the court and the regulatory agency subscribing to it, what the procedures would be for cross examination, how the public would participate, whether the system already works well enough. In short, the meeting was a mélange of speculation. It is probably accurate to say that Dr Kantrowitz, who heads a science court task force set up by a now-disbanded White House science advisory committee, will get a little money to do a science court experiment with a regulatory agency. That's what he intends to do. In fact, the colloquium's point was to hash over the elements of such an experiment.

Two concrete issues were discussed around which an experiment might be devised: food additives and nuclear power. Both issues have enjoyed and lamented over huge outpourings of fact, opinion, and acrimony over many years. In both cases the matter boiled down to the free flow of information —facts withheld by government and industry that no science court could pry loose. And anyway, one could make a fairly substantial case for the "fact" that science courts already exist— through panels serving regulatory agencies, through the National Academy of Sciences, through existing legal courts, in other words through a system within the American democracy that, after all is said and done, does indeed spot the scallawags.

It is certain that the experiment will be tried. The President's science adviser, Guyford Stever, gave it cautious endorsement. Even the Commerce Secretary, Elliot Richardson, said it might as well be tried, although

Science court: specifications

A top-level science advisory committee, established by President Ford last year to prepare the way for the re-establishment of a White House science policy office, recommended that the Science Court idea should be given serious consideration. It established a task force, chaired by Dr Arthur Kantrowitz, which has drawn up the following specifications for the court:

Initiation

1. The experiment will begin with agreements between the Science Court Administration (SCA), the host institution and the funding institution concerning the plans for the experiment.
2. The first step will consist of contacts with regulatory agencies and others to search for a suitable issue. The first issue will be presumed to be bi-polar and will be presumed to be a value laden decision which must be made by the agency and in which the scientific facts are apparently in doubt.
3. An agreement with the regulatory agency to supply necessary legal powers for uncovering non-public information if necessary.

Organisation

4. The SCA, equipped with an issue and funds, will seek Case Managers (CMs) for each side of the issue. The work of the CMs will be funded by the SCA.
5. The SCA will issue procedures, suggested referees, and a panel of prospective judges.
6. The CMs will review these suggestions. The experiment will go forward only after both CMs agree on the referee, the judges and the procedures. A signed agreement to proceed will commit the SCA, the funding agency, the regulatory agency, the CMs, the judges, and the referee.

Suggested procedures

7. The CMs formulate a series of factual statements which they regard as most important to their cases. Such statements must be results or anticipated results of experiments or observations of nature.

The statements should be ranked in order of importance assigned by the CM.
8. The judges examine each statement to determine that it is a relevant scientific fact.
9. The CMs then exchange statements. Each side is invited to accept or challenge each of the opponents statements.
10. The list of statements accepted by both sides will constitute the first output from the SC.
11. Challenged statements are first dealt with by a mediation procedure in which attempts are made to narrow the area of disagreement or to negotiate a revised statement of fact that both CMs can accept.
12. The mediated statements are added to the SC's output. Those statements which remain challenged are then subjected to an adversary procedure.
13. CMs prepare substantiation papers on statements remaining challenged and transmit these to the judges and the opposing CMs starting with the first (most important) challenged statement.
14. The substantiation is cross-examined by opposing CMs and judges and contrary evidence is presented and cross-examined.
15. A second attempt to negotiate a mediated statement is made and if successful this statement is added to the Science Court's output.
16. If this is not successful the judges write their opinions on the contested statement of fact.
17. This procedure is repeated for each of the challenged statements.
18. The accepted statements plus the judges' statements constitute the final output of the procedure.

it shouldn't be confused with a court of law. Stever did imply, however, that one shouldn't expect too much.

The mythology behind the science court concept does deserve an analysis that the colloquium did not consider. The question concerns reasons why the science court idea is deemed so urgent as to have a whole colloquium called to discuss it. Industrialists seem to want it because they are convinced that strident opposition to technology by environmentalists are stifling their own freedom to make fair profits. Scientists and engineers seem to be for it because it gives them the chance to establish order in forums often run emotionally. Environmentalists and public interest figures are against it because they fear their positions will be muted by a scientific elite that has little feeling for human needs. And lawyers are against it because they feel court procedures, if done right, hear all sides to a case, within human limits of patience, tolerance, and intelligence.

On the scope of reality, the science court seems of little importance beyond a possibly interesting intel-

lectual exercise. Regulatory agencies make literally dozens of decisions daily. Hundreds of scientific panels are called to aid in those decisions—little courts, if you will. The National Academy of Sciences runs a series of Science Forums every few weeks or so in which the public actually does debate with scientists the validity of scientific findings relevant to public issues. The administrators of the Science Forum aren't pretentious enough to believe their procedures heavily influence decisions. But some follow-up studies do indicate that the debates raise the personal and collective consciousness to a degree satisfactory to anyone wise enough to understand that people aren't swayed very easily.

The trouble is that no one quite knows what to think of the Science Court. It is a difficult target to attack because the subject is virtuous. Many simply don't feel it is worth much. One might call the feeling the accumulated wisdom of those who have been through the course of using scientific facts in the pursuit of the common weal.　　　　　　□

SWEDEN

Swept in on the green wave?

From Stockholm, Wendy Barnaby assesses what the result of the recent Swedish general election could mean for science in that country

AFTER 44 years in power, Sweden's Social Democrats have been defeated at the polls. Their general approach to science was not discussed in the election campaign. But scientific assessments became very important in the debate which dominated its final stages: whether or not to push ahead with the Social Democrat's plan to make Sweden the world's largest producer of nuclear energy *per capita* by 1990. The scientific input was dramatised by a telegram sent two days before the election by the American Union of Concerned Scientists to the Prime Minister, Olof Palme, challenging his view that nuclear waste disposal problems are on the way to being solved.

Although the non-socialist parties which will now form a coalition government are split on the nuclear issue, the pre-election battle lines were drawn between the Social Democrats on the one hand and the anti-nuclear energy Centre Party, the largest non-socialist party, on the other. And in spite of the enormous organisational and governmental machinery at the Social Democrats' disposal, it was the arguments of the non-establishment scientific community which ultimately appealed to the Swedish voters.

The Centre Party, traditionally the political voice of the Swedish farmer, has in the past few years been the champion of the so-called 'green wave': demands for decentralisation of population and power, environmental protection, the careful use of finite resources and—in the energy field—the development of reliance on renewable resources such as wind and solar power. According to the party's spokesman on scientific affairs, Bengt Sjönell, one of the new government's aims will be to bring the Swedes into balance with nature as far as energy resources are concerned. The first test of how this rather idealistic hope is to be realised will come less than 2 months after the formation of the new government, early in October, when the squat Barsebäck 2 nuclear power reactor, becomes ready for fuel insertion.

The Centre Party's leader (the new Prime Minister), Thorbiörn Fälldin, is personally and publicly committed to stopping the loading of fuel into any more reactors. (He has also promised close down those five reactors already in operation.) Nobody doubts

the strength of his commitment. But the problem with Barsebäck 2 is how fuel loading can be prevented. One proposal is to prohibit the insertion of fuel by passing a succession of laws each valid for one month at a time until compensation can be negotiated with the reactor's owners, who have demanded $445 million from the government. The trouble with this is that the reactor is owned by a private company, Sydkraft, and for a non-socialist government to make its legislative debut with such regulation of private industry would be politically unpalatable. To get around this difficulty, it has been suggested the Nuclear Power Inspectorate—a state body which checks reactors under construction and in operation to see that they conform to agreed standards—could prohibit fuel loading at Barsebäck 2. But that organisation is itself not at all happy with the idea. Its brief covers purely technical areas, and although the checklist for the reactor has not yet been entirely worked through, there have so far been no technical hitches. Dr Arne Hedgran, a representative of the inspectorate recently made it quite clear that the organisation does not want to become involved in the government's political problems.

The tangle over Barsebäck 2 is the most pressing problem faced by the new government; not only because of the time factor but also because the Centre Party's credibility will be greatly affected by its handling of the situation. In its very first days of power it will have to come to grips with the issue held to be largely responsible for its victory.

The influence of the already-powerful environmentalist groups will no doubt increase under the new government, partly because of official willingness to listen, but also because of significant gains by the environmentalists in the local elections held at the same time as the national ones. One such local result has particularly far-reaching national and international implications. A victory by groups opposed to the mining of uranium near Billingen, 350 km south-west of Stockholm, means that uranium reserves estimated to be the West's largest in the next economical price range cannot now be exploited for at least three years. The mining firm LKAB had been hoping to mine them either for domestic use or for export.

Beyond the immediate problems, what sort of initiatives in science policy can be expected from the Centre Party? It should be mentioned that Sweden

Fälldin, committed

has no ministry of science: the administration of science instead falls to various other ministries. Those most concerned are Education, Industry and Agriculture, but even they exert little pressure on the direction of research. Once funds have been allocated to the extraordinarily varied array of institutes and research bodies, each research group is practically autonomous in deciding how they are to be spent. Consequently, it is often hard to see whether Sweden has any science policy as such at all.

One trend which is, however, apparent in all this diversity is the priority given to applied research over basic research. This emphasis has been responsible for the present plight of so-called basic technical research, which has been practically squeezed out of existence in Sweden. Bengt Sjönell recently declared that the Centre Party wants to strengthen the relative position of basic research, and stressed specifically that support for basic technical research would be increased. But the party's intentions have not yet been expressed in detailed proposals, or even in concrete plans, though in tertiary scientific education, the party will try to tempt students back to research in the natural sciences, whose current unpopularity has been raising questions about Sweden's long-term scientific research capabilities. But Sjönell seems unaware of the potential of the International Energy Institute due to begin work here next year. Although the government will have no control over the work programme at the institute, it is a reasonable bet that much of the research done there will be directly relevant to official aims. And for a government whose interest in science is concentrated in the energy field, the value of such research should not be underrated. In other areas of Swedish science, the prognosis is business as usual. ☐

IN BRIEF

NIH budget veto overridden

A few days before it adjourned for the November elections, the US Congress firmly overrode a Presidential veto of a budget bill for the National Institutes of Health (NIH), thereby increasing NIH's biomedical research funds by more than $200 million in the fiscal year which began on October 1. The bulk of the increase will go to the National Cancer Institute (NCI), whose budget will soar from $762 million to $815 million. Also set for a large increase is the National Heart and Lung Institute, which will get $397 million, up from $370 million last year. The final budget levels represent a considerable victory for supporters of the cancer programme, for the Ford Administration had recommended that the NCI's budget be held approximately constant and that the other NIH institutes be given modest increases.

Air Act problem

The US Congress has handed the automobile industry a tangled legal problem by failing to pass amendments to the Clean Air Act before it adjourned last week. The amendments would have relaxed emission control standards for 1978 model cars, which the industry is already gearing up to produce. Members of Congress failed to agree on the bill, and it died when the session ended in the early hours of Saturday morning. Thus, unless the new Congress approved laxer standards when it convenes next January, the industry will be faced with the choice of producing illegal cars or closing down. That, in fact, is exactly the situation that the industry has been trying to engineer. It believes that the threat of wholesale closures and high unemployment in Detroit will be sufficient to force the new Congress to meet its various demands.

UK changes

Under the rearranged provisions for science policy formulation in Britain, the UK government has appointed a 37-year-old biochemist from Essex University, Professor John Ashworth, to the Cabinet Office's Central Policy Review Staff for a two-year period.

Elsewhere, Professor J. L. Gowans, 52, will be the next Secretary of the UK Medical Research Council, taking over from Sir John Gray in April 1977. He is presently Director of the MRC's Cellular Immunology Unit.

ALTHOUGH the sixth report of the Royal Commission on Environmental Pollution, and various informed comments on it, have shown that there is widespread concern in Britain about the rapid development of nuclear power in general, and of the fast breeder reactor in particular, those responsible for the safety of atomic energy and nuclear fuels have come well out of the controversy. Engineers, scientists and those working in nuclear power stations have behaved responsibly in this respect, and have scrupulously observed the most rigorous safety precautions. Many of us may doubt whether we need this massive development in electrical generation which the Department of Energy thinks necessary, when we already have 50% more capacity than the peak load, and when demand is falling, but that is another matter. There is little doubt that if the nuclear generating industry is expanded as planned (*sic*) the same high standards of care will continue to be exercised, though the statistical chances of accidents must inevitably increase.

Therefore if we are to have more nuclear power stations, we must constantly review and improve safety precautions. At present there is a series of safety regulations laid down and agreed internationally; unfortunately some of these are not entirely practical. Thus the specifications for the containers, each weighing some 45 tonnes, in which nuclear fuel is shipped around the country, are intended to ensure that the risks of an escape of radiation or radioactive materials are very small indeed. The vessels are designed to resist such mishaps as a fall of several metres, though there is doubt whether they are strong enough to remain intact if the train carrying them was derailed at a high speed.

The regulations state that they must be able to resist a temperature of 800 °C, uniformly applied to the

---

Protection practice
KENNETH MELLANBY

---

whole of their surface. Unfortunately the experts of British Nuclear Fuels Ltd have found it impossible to devise a technique by which the containers can be subjected to the conditions laid down by the international authorities. They have spent—or wasted—some half a million pounds trying to devise a method of giving exactly the correct exposure to this high temperature. As this sort of temperature exposure appears to be impossible to produce, it is difficult to understand why this particular standard was set. We wish to be sure that our nuclear fuel is safe when the containers are exposed to the sort of hazard which, in practice, is likely to be encountered. Uniform conditions of 800 °C continued for twenty minutes do not constitute one of these. It would surely be better to devise a "standard fire" similar to one likely to be experienced by the nuclear fuel when in transit, and to put the containers into it.

A similar attitude to that which sets up these unreal safety standards may sometimes be demonstrated by those responsible for our defence. Some years ago conservationists were urging the War Office to give up an area of Britain's coastline, where the sand dunes were of great natural history interest. The War Office was reluctant to part with the land, giving as an excuse that it was of the greatest importance for military training because it was "unique" and irreplaceable by any other area which was available. When I heard this I could not help wondering how it was to be used for training our forces. If it was indeed unique, then any military exercise performed there would have little relevance to those done on other, quite different, terrains. In fact the only value of this special piece of coastline would be in order to train our forces to defend it. Surely training would be better done on a more typical area, with conditions similar to those found in many parts of the globe?

We need to be protected from danger by safety standards for hazardous industrial processes, and by the possession of efficient military defences. In both cases we should first decide exactly what we need to be protected from, and then we can set up practicable standards to which we can work.

news and views

Doping amorphous silicon

from Andrew Holmes-Siedle

Recently (see *News and Views,* **260,** 667; 1976) a group at the University of Dundee (Spear *et al., Appl. Phys. Lett.,* **28,** 105; 1976) reported that, for the first time, a p–n structure had been made from amorphous silicon only. This achievement demonstrates that, contrary to common belief, amorphous material can be "doped" by impurities. Such a finding effectively eliminates one of the hypotheses which has been aired to explain the suppression of doping in amorphous materials—namely that the valence bond of the dopant atom (which cannot be satisfied within a constrained crystal structure) can usually be accommodated and satisfied by an atom of the disordered matrix. Here, however, is a truly amorphous silicon matrix which can be made either p–type or n–type by the addition of boron or phosphorus, although more dopant is needed than for the case of crystals.

Spear and LeComber have now published some more basic investigations on conductivity and field effects in a much simpler structure, namely a silcon film of only one conduction type (Spear and LeComber, *Phil. Mag.,* **33,** (6) 935-949; 1976) and their new account shows that my earlier comments on the "apparent inefficiency of doping" and my implication that disorder in these silicon networks was still largely "negating" the electrical activity of the dopant atoms was an oversimplification. In fact, quite a large fraction of the dopant atoms is ionised, as we shall see below.

Spear and LeComber deposit the silicon films by glow-discharge decomposition of silane on glass, using phosphine or diborane as dopant gases. This is a well-known technique but is the first intensive study of the product. They found that the conductivity of the films could be controlled in unprecedented fashion for amorphous materials, from 10^{-7} to 10^{-2} (ohm cm)$^{-1}$.

In the past, sputtered films have usually had very low conductivity and any changes achieved (for example by heat treatment—see stippled area of figure) were caused by changes in the density of intrinsic defects, sometimes called "dangling bonds", rather than by true doping effects. Such ability to control conductivity could open up the technological uses of thin-film amorphous silicon—a very desirable thing because of the cheapness and large possible areas of such films. However, there are some formidable, fundamental and technological barriers to be surmounted before devices competitive with single-crystal silicon forms can be created. The efficiency of doping as it affects conductivity is still quite poor, for some fundamental reasons. First, the mobility of carriers in the disordered matrix is lower than for single-crystal semiconductors. Second, many carriers are immobilised in a class of energy states special to amorphous semiconductors ("mid-gap states"). The achievement of Spear and LeComber is to reduce these states until at least a small proportion of the electrons and holes, freed from the dopant atoms, appear in conduction states. Nevertheless, the poor relative efficiency of dopant atoms in producing conductivity is clearly shown up in the figure, adapted from the new measurments of Spear and LeComber (crosses) and other data (full lines, dotted lines). N_D^+ was estimated tentatively by Spear and LeComber from the temperature dependence of conductivity in the amorphous films, with supporting evidence from chemical analysis and photoconductivity measurements. The shaded area shows the difference between amorphous and single-crystal material. While further work may bring these curves somewhat closer together, there is no immediate clue as to how this may be done. In the new material, the density of electron states

A FOOTNOTE to the work reported here is now required because, as might have been expected, the possible use of amorphous silicon films to make photovoltaic p-n diodes has not been ignored. The first to publish is RCA Corporation; others will probably follow shortly. The RCA workers, D. E. Carlson and C. R. Wronski (*Appl. Phys. Lett.,* **28,** 671; 1976), have made thin-film, back-surface amorphous-silicon solar cells on glass by a deposition process essentially the same as Spear and co-workers at Dundee (glow-discharge deposition of silane gas) but the RCA films used are thicker than the Dundee films and have an undoped ("intrinsic") region of thickness about 1.5 μm between the p and n-type regions. The 3.5 cm^2 cells produced have a terrestrial solar conversion efficiency of 2.4% and the authors estimate that the theoretical efficiency of their p-i-n structure should be 14–15%. Thus, the unexpected finding that useful junction barriers can be rather easily produced in amorphous silicon may lead to a surge of effort to produce low-cost, large-area solar energy converters by this method. The economic advantages of thin-film devices over ingot-grown semiconductor devices have been stressed and we may now be avoid the problem of the polycrystalline thin-film approach.

Though surprising advances have recently been reported in fabrication of polycrystalline silicon cells (5% efficiency claimed for large-area polycrystalline films deposited on graphite, *Electronics,* 33, June 24, 1976) the grain boundaries, which constitute a completely unwanted barrier to carrier transport in such films, are dispensed with in amorphous layers.

in the middle of the gap may be as low as 10^{17} cm^{-3} eV^{-1}. This is a huge improvement over previous films, which had densities as high as 10^{20} cm^{-3} eV^{-1} at mid gap, but how much further can we go towards the case of single-crystal silicon, with a density of virtually zero? Some opinion says that the gap in the figure probably cannot be closed much more, but it is still a fascinating question.

Many other fascinating questions will doubtless be raised during further basic physical studies on the new material. With diodes, for example, recombination in amorphous networks can be explored, recombination being the property which most affects gain in transistors. With the doping techniques, we can refine our models of electron and hole transport in regimes not possible before and thereby redress our present ignorance about the environment of substitutional impurities in disordered networks. Out of such work could grow the expertise necessary to exploit this second generation of amorphous films.

Comparison of conductivity against doping curves for single crystal silicon and amorphous silicon (a-Si).
Chlorophyll dimer and triplet states – key roles in photosynthesis?

from Godfrey Beddard

It has been known for some years that the initial photochemical act in photosynthesis is the formation of an oxidant P$^+$, and a reductant X$^-$ resulting from excitation of the reaction centre PX, either directly by light absorption or indirectly by energy transfer from accessory pigments. This reaction centre is composed of a special chlorophyll complex, the electron donor, closely associated with an electron acceptor.

The nature of the reaction centres has been the subject of much interest and speculation and recently experiments using optical spectroscopy and magnetic resonance techniques have resulted in a detailed picture of the bacterial reaction centre P$_{870}$ and the characterisation of the two reaction centres P$_{700}$ and P$_{680}$ of green plants. Chlorophyll dimers have been implicated in all three types and recently electron spin resonance (ESR) spectra exhibiting the CIDEP phenomenon suggest that chlorophyll triplet states are also involved, as described McIntosh and Bolton (*Nature*, **263**, 443; 1976).

Picosecond spectroscopy on bacterial reaction centres has revealed transient absorption changes, implicating both bacteriochlorophyll (BChl), and macteriopheophytin (BPh). The transient forms in 8 ps and decays with a 150 to 250 ps lifetime concomitant with P$_{870}^+$ X$^-$ formation. (Rockley, *et al. Proc natn. Acad. Sci. U.S.A.*, **72**, 2251; 1975: Kaufmann, *et al. Science*, **188**, 1301; 1975). Fajer *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 4956; 1976) proposed that the primary electron acceptor was not an iron–ubiquinone complex as was previously thought, but was instead bacteriopheophytin. In an elegant experiment Fajer *et al.* reproduced the transient absorption spectrum of the reaction centre from the difference spectrum; (BChl)$_2^+$ − (BChl)$_2$ plus BPh$^-$ − Bph. Agreement was found for all absorption bands from 350 to 1,250 nm as a transient absorption of (BChl)$_2^+$ has been detected at 1,250 nm. (Dutton *et al., FEBS Lett.*, **60**, 275; 1975).

Triplet state zero-field parameters have enabled Clark *et al.* (*Biophys. Biochem. Res. Commun.*, **71**, 671; 1976) to determine that the two BChl molecules *in vivo* are tilted at 48° and rotated by 78° to one another. Further-

more ENDOR linewidths indicate dimeric BChl species are present, (Feher, *et al., Ann. N.Y. Acad. Sci.*, **244**, 239; 1975; Norris, *et al., ibid.*, 239; 1975) and in addition electron spin polarisation indicates that the primary act is a radical pair formation. (Thurnauer, *et al., Proc. natn. Acad Sci. U.S.A.*, **72**, 3270; 1975). These experiments support a model of the bacterial reaction (in *Rhodopseudomonas sphaeroides*) in which the charge separation process forms the ion pair (BChl)$_2^+$ BPh$^-$ before the reduction of the ubiquinone "primary" acceptor.

The chlorophyll-*a* species of photosystem I reaction centres—P$_{700}$—has a bleachable absorbance at 703 nm and a characteristic ESR signal. *In vivo* ENDOR linewidths indicate that P$_{700}$ contains a (Chl)$_2$ species (Feher, *et al., op. cit.*; Norris, *et al., op. cit.*), and Shipman has recently proposed that this dimer has the form (Chl–ROH)$_2$; with R = H, ethyl or protein. Shipman, *et al., Proc. natn. Acad. Sci. U.S.A.*, **73**, 1791; 1976). This symmetrical dimer has absorbance and ESR spectra similar to P$_{700}^+$. The oxygen in ROH bonds to the Mg of Chl and the

hydrogen bonds to ring V carbonyl of the other Chl. As ROH, RNH, RSH compounds also form dimers this presents the intriguing idea that the *in vivo* dimer may be bound to similar groups in a protein but at present no experiments have been reported to test this idea.

Perhaps the most interesting observation on P_{700} is a transient electron proton resonance (EPR) emission spectrum produced by a single light flash on chloroplasts at room temperature. (Blankenship, *et al., Proc. natn. Acad. Sci. U.S.A.*, **72**, 4943; 1975). The EPR signal is thought to be that of the primary acceptor as it does not correspond to P_{700}^+ or a ferredoxin.

The emission is caused by the two spin states, normally thermally populated to 0.1% of one another, obtaining a significant population difference as a result of a particular chemical reaction favouring one state over the other. This phenomenon is called chemically induced dynamic electron polarisation (CIDEP). Immediately after the radical anion of the acceptor is formed the spin states still have the same populations as the anion's precursor and a CIDEP signal is observed until spin lattice relaxation equalises the spin populations. A triplet state of Chl is thought to be responsible for the emission from photosystem I, as a radical pair, which can also generate CIDEP are unlikely to diffuse together in the reaction centre.

There is still much controversy about the identity of the primary acceptor for P_{700}. Malkin *et al.* (*Biochim. biophys. Acta*, **430**, 399; 1976) maintain that the acceptor is a ferredoxin, but McIntosh and Bolton (*Biochim. biophys. Acta.*, **430**, 555; 1976) and Evans *et al.*, (*Nature*, **256**, 668; 1975) dispute this and claim that a species with ESR signal $g=1.76$ is the primary acceptor and that ferredoxin has a secondary role. The relationship of the signal seen by Blankenship to these acceptor signals is not known. The evidence is not as complete as with the bacterial reaction centre but the initial charge separation in photosystem I appears to produce a $(Chl)_2^+$ species and an unidentified radical anion before the ferredoxin is reduced.

Much less is known of photosystem II reaction centres, P_{680}, than of P_{700}, although there is good evidence that P_{680} is the primary donor, possibly a chlorophyll dimer (Pulles, *et al., Biochim. biophys. Acta*, **440**, 98; 1976). The observation, by McIntosh and Bolton, of a CIDEP emission from Chl in photosystem II is thus of particular interest as this signal can only arise from a Chl triplet state at the temperatures used. They suggest that the triplet state forms very rapidly from the singlet by the formation of a Chl^+

Chl^- species. The primary acceptor would then have to be adjacent to the dimer in order to accept the electron at a rate much faster than the charge recombination for efficient charge separation to occur.

Many similarities between reaction centres are now emerging. All involve chlorophyll dimers; at least two, and perhaps all, contain short lived "transient" acceptors between the dimer and the "primary" acceptor which is perhaps a device to prevent rapid charge recombination of the ion pair. Although both P_{700} and P_{680} appear to involve triplet states formed, perhaps very quickly, after excitation of the dimer species the reasons for preferring triplets over singlets are unknown. Consequently picosecond spectroscopy will be invaluable in observing transients produced in the initial processes and our present knowledge of reaction centres should provide impetus to produce model systems to mimic photosynthetic processes. □

Homostable operons?

from E. G. Richards

READERS who glance through the pages of the more theoretical journals will be aware of the immense activity over the past 15 years on the statistical mechanical basis of the melting of DNA. Certainly every well-informed undergraduate will know that DNA undergoes a cooperative helix coil transition when heated that gives rise to a sharp melting curve. However theory suggests that things are not quite that simple. For instance, a hypothetical DNA molecule consisting of a region of 1,000 A–T base pairs followed by a similar one of G–C pairs would give a melting curve consisting of two sharp steps. To produce a sharp step, theory suggests, requires a 'homostable' region of 500 or more base pairs with no sequences of more than a few adjacent A–T or adjacent G–C base pairs. A DNA molecule consisting of several such homostable regions would then melt in a series of sharp steps, and the melting temperature of each step should reflect the base composition of the corresponding region.

Another and more informative way of depicting melting behaviour is by the differentiated melting curve in which sharp steps now appear as sharp peaks. In recent years much expertise and ingenuity has been expended in constructing equipment capable of producing such curves at high resolution so that the fine structure of a melting curve occurring over 10 °C or so could be resolved into a dozen or more sharp peaks each a degree or so in width.

Wada and Tachibana, in a paper in *Nature* (**263**, 439; 1976) note that short DNA species do indeed manifest such fine structure in their differentiated melting curves and, moreover, that the melting temperature of the individual peaks does indeed bear the expected relation to the base composition of the corresponding DNA region as revealed by spectral analysis. In longer DNA species, presumably consisting of many homostable regions with closely similar stabilities, the fine structure is less apparent.

These authors then go on to consider the behaviour in more detail of a short DNA (fd phage, 6,000 base pairs) and fragments produced from it by the restriction enzyme R*Hin*HI.

First, the intact DNA (RF linear) is shown to have a differentiated melting curve consisting of more than a dozen sharp peaks distributed over a 10 °C melting range. The product formed by the action of the restriction enzyme and consisting of three fragments gives a broadly similar curve. When the three fragments were separated by polyacrylamide gel electrophoresis they individually gave curves with considerably fewer peaks. Nevertheless, when the three curves corresponding to the three fragments were summed, the result was closely similar to the curve of the mixture.

These results suggest that the peaks in the differentiated melting curves arise from homostable regions situated at specific locations in the molecule. It would appear from the relative sizes of the peaks and from the fact that splitting is observed that some peaks correspond to several homostable regions with closely similar stabilities.

A detailed comparison of the curves for the intact molecule and for the mixture of its fragments suggests that one homostable region may affect the melting temperature of others so that peaks in one of the curves may be split in the other by moving to slightly different temperatures. It is tempting to speculate that such interactions are between adjacent homostable regions, in which case it might be possible to map the regions along the molecule. Certainly the effect presents interesting statistical mechanical problems.

Wada and Tachibana end by speculating as to whether these homostable regions have some biological role. The data suggest that each operon can contain only a few and perhaps only one homostable region, and the authors suggest that the regions might play some part in recombination. They also note that wobble interactions in translation could well mean that homostable regions and active polypeptide sequences could be selected for simultaneously. □

Photosynthetic prokaryotes

from Venetia A. Saunders

The second international symposium on photosynthetic prokaryotes and first meeting of the Federation of European Microbiological Societies was held at the University of Dundee, Scotland, on August 22–28, 1976. It was organised by G. A. Codd, and W. D. P. Stewart of the Department of Biological Sciences, University of Dundee.

MUCH interest in the photosynthetic prokaryotes derives from their evolutionary and ecological significance. Moreover their metabolic versatility makes them particularly attractive research tools for studying processes involved in photosynthesis and nitrogen fixation. It is customary to recognise two groups of photosynthetic prokaryotes, the photosynthetic bacteria and the cyanobacteria (blue-green algae). The cyanobacteria typically exhibit oxygenic photosynthesis with water as the ultimate electron donor. On the other hand photosynthetic bacteria do not evolve oxygen, but utilise oxidisable substrates besides water (notably reduced sulphur compounds or organic compounds) as electron donors in photosynthesis. Now it seems that certain blue-green algae can grow at the expense of reduced sulphur compounds. Are these compounds also utilised by blue-green algae as electron donors in photosynthesis? R. Castenholz (University of Oregon) reported that sulphide could act as a photoreductant in certain blue-green algae from hot springs, but only when photosystem II was switched off. However it is not yet clear whether this process can be used to support growth. H. Utkilen (University of Oslo) demonstrated oxidation of thiosulphate by the blue-green alga *Anacystis nidulans*. He proposed that when the supply of ATP or of electrons from water is curtailed by low light intensity, *A. nidulans* utilises thiosulphate as an electron donor in a manner analogous to that of photosynthetic bacteria.

The primary photochemical reaction in bacterial photosynthesis involves transfer of an electron from bacteriochlorophyll to the primary acceptor. In the purple non-sulphur bacterium *Rhodopseudomonas sphaeroides* this occurs in a pigment-protein complex, the reaction centre. Recently intermediate short-lived states of this primary event have been identified. Interpretation of the nature of such states has been aided by picosecond

kinetic measurements. R. Cogdell (University of Glasgow) and colleagues propose that both bacteriochlorophyll (magnesium porphyrin) and bacteriopheophytin (hydrogen porphyrin) have a role in the primary photochemistry (see *Proc. natn. Acad. Sci. U.S.A.*, **72**, 2251; 1975). F. Reiss-Husson (Gif-sur-Yvette) described a procedure for incorporating reaction centres from *R. sphaeroides* into lecithin liposomes. Such an *in vitro* system should be convenient for studying the contributions of various electron transport components to the reconstitution of photosynthetic activity.

In photosynthetic bacteria the light-harvesting pigments are either accommodated with the energy conversion system on a topologically complex cytoplasmic membrane, or located in different structures of non-unit membranes called chlorobium vesicles. R. C. Fuller and C. Boyce (University of Massachusetts) reported that in the green bacteria reaction centre, bacteriochlorophyll *a* but not the bulk light-harvesting (antenna) chlorophyll is associated with the cytoplasmic membrane. The antenna chlorophyll is restricted to the chlorobium vesicles, which are considered to press up against, but remain distinct from, the cytoplasmic membrane. Light energy is transmitted from these vesicles to the reaction centre. *Chloroflexus* the only known organism with chlorobium vesicles capable of growing aerobically in the dark as well as anaerobically in the light, should accordingly prove an attractive system for investigating the development of this type of photosynthetic apparatus.

Nitrogen fixation has been more extensively studied in the cyanobacteria than in the photosynthetic bacteria. Furthermore the ability of cyanobacteria to fix nitrogen may explain symbiotic associations of certain blue-green algae in lichens and liverworts. Morphological and physiological modifications of the blue-green algae accompany these associations as reported by W. D. P. Stewart and colleagues (Dundee University). Significantly such symbiotic blue-green algae fix nitrogen more efficiently than in their free living state. The heterocyst is the main site of nitrogen fixation in certain filamentous (heterocystous) blue-green algae. Neither CO_2 fixation nor photosynthetic oxygen evolution occurs in heterocysts, such activities being restricted to vegetative cells. E. Tel-Or (University of Dundee) proposed that the defects in the photosynthetic machinery of heterocysts were probably due to the low level of ribulose diphosphate carboxylase, the cardinal enzyme in CO_2 fixation, and depletion of manganese required for

the water splitting reaction of photosynthesis.

Heterocysts develop when blue-green algae are grown in the absence of combined nitrogen. A definite heterocyst pattern emerges throughout the algal filaments. The development of such patterns may well be dependent not only on intracellular but also intercellular reactions. J. C. Meeks (Michigan State University) suggested that some diffusible product of mature heterocysts, possibly glutamine or a derivative, may inhibit nearby cells from differentiating into heterocysts. However the heterocyst pattern is established before nitrogen fixation occurs. What then triggers the developmental events? Studies on the mechanisms of induction of enzymes pertinent to the process of differentiation, as pointed out by R. Haselkorn and N. Woods (University of Chicago), may further elucidate this problem.

The promise of the genetics and molecular biology of photosynthetic prokaryotes is gradually being fulfilled. A novel gene transfer system has been discovered in *Rhodopseudomonas capsulata* by Marrs, (see *Proc. natn. Acad. Sci. U.S.A.*, **71**, 971; 1974). Furthermore this system has been used for mapping genes concerned with photopigment synthesis (B. Marrs, St. Louis University) and also for manipulating genes for nitrogen fixation (J. D. Wall and H. Gest, Indiana University) in this organism. The ability to manipulate genes in photosynthetic prokaryotes will lead to a more profound understanding of the control of such processes as photosynthesis and nitrogen fixation.

In discussing the evolution of the cyanobacterial genome, M. Herdman (University of Dundee) reported a concomitant increase in genome size with increasing morphological and biochemical complexity for these organisms. He speculated from the results that genomes of the cyanobacteria could have formed by multiplication and divergent evolution of copies of a small ancestral genome.

R. P. Ambler (Edinburgh University) reporting sequencing studies on *c*-cytochromes of eukaryotic and prokaryotic photosynthetic systems, urged caution in the interpretation of phylogenetic relationships based on structures of existing proteins. Indeed differences and similarities between species may well have been blurred by the agency of genetic exchange.

A fitting finale to the meeting was the fascinating report by R. A. Lewin (University of California, La Jolla) of prokaryotic "green algae/bacteria". These unicellular algae, found in association with ascidians, possess a unique combination of characteristics, predominantly prokaryotic, but the organ-

isms contain both chlorophyll *a* and *b* as found in eukaryotic plant cells (see *Nature*, **261**, 697; 1976). Could these organisms or relatives be ancestral forms of photosynthetic plastids of eukaryotic cells? Whether this type of "prokaryote" is a missing link or not remains to be seen, but it is likely to be a link between this and the third symposium. ☐

Anti-juvenile hormone and pest control

from a Correspondent

THE preparation of active extracts of juvenile hormone from the American cecropia silkmoth 20 years ago suggested the possibility of the eventual use of synthetic hormone as an insecticide. The original idea was that this could lead to the appearance of non-viable intermediates between larvae and adults. The discovery, 10 years later, of the chemical nature of juvenile hormones (of which three varieties have so far been described) stimulated an immense amount of synthetic chemistry in this field. A vast range of products has been produced, some of them not at all closely related chemically to the natural hormone; some, far more active than the natural substance, have been put on the market as insecticides.

The obvious theoretical objection to the juvenile hormone as an insecticide —that it will tend to produce giant larvae which may be more destructive than the ordinary sort—has proved justified in some cases. On the other hand, it has been proved empirically that some of these products are effective for rather special purposes, and some of them have a sterilising action on the adult female or disrupt the development in the resulting eggs. By and large, however, the results have been somewhat disappointing.

It was suggested early that an anti-juvenile hormone, which could cause precocious metamorphosis, might be a more successful kind of insecticide. In a recent paper William S. Bowers and his colleagues at Geneva, New York (*Science*, **193**, 542–547; 1976) report a search for such products in a long series of plants, by extracting the less polar organochemical components in a mixture of ether and acetone. From the common bedding out plant *Ageratum houstonianum* they obtained a product which had very active anti-juvenile hormone properties when applied to immature Hemiptera. It in-

duced precocious metamorphosis at the ensuing moult when applied to first, second or third-stage larvae of the milkweed bug *Oncopeltus;* and similar results were obtained in the cotton stainer *Dysdercus.*

The active principle was purified, analysed and synthesised. It contained two simple chromenes, 7-methoxy-2, 2-dimethyl chromene and 6,7-dimethoxy-2, 2-dimethyl chromene (Fig. 1), which were already known from plant extracts. On account of their ability to cause precocious metamorphosis these substances have been named precocene 1 and 2. Precocene 2 is about ten times more active than precocene 1.

Precocene 1   Precocene 2
Eggs of Hemiptera fumigated with the precocenes gave rise to larvae which developed normally for two instars and then moulted to precocious adults. The precocious adults, however produced, had well formed ovaries but they never matured to form ripe eggs —a process for which juvenile hormone is necessary. Application to adult females caused regression of the ovaries; and late treatment had an ovicidal action, the nature of which is unknown.

A hundred years ago

The Colorado potato beetle *Leptinotarsa*, on the approach of winter, ceases to secrete juvenile hormone. It enters reproductive diapause, egg development is suppressed and it burrows into the soil. When the adult *Leptinotarsa* was treated with precocene it was forced, apparently permanently, into diapause. The mode of action of the precocenes is not yet known; there are many steps in the synthesis, physiological action or breakdown of the juvenile hormone, any of which could be responsible for the disruptive effects observed.

It remains to be seen whether materials of this kind will prove effective for practical control. The fact that all their effects will diminish insect damage, and that all the precocious females are sterile, are favourable factors. The substances obtained so far have induced precocious metamorphosis only in Hemiptera, and not in Holometabola. But they have sterilised adult females among Diptera and Coleoptera. The discovery of anti-juvenile hormones specific for selected pest species is an atractive possibility. ☐

Specific toxin receptors in plant disease

from I. M. Smith

THE fungi which parasitise plants are commonly host-specific; one pathogenic species will often only infect a limited range of closely related plant species or even only some genotypes within a species. The molecular basis of this specificity is one of the outstanding problems in physiological plant pathology. Some progress has been made in the type of disease in which successful infection depends on the release by the fungus of phytotoxic metabolites which may be host specific. One notable example of this is the Victoria blight of oats (caused by *Helminthosporium victoriae*), in which the toxin victorin has high specific activity only on certain oat genotypes, which are at the same time the only ones susceptible to infection. Similarly, *H. sacchari* produces the toxin helminthosporoside which is only toxic to susceptible lines of sugarcane. In this case, Strobel has reported a membrane protein which binds the toxin, but only in susceptible lines. Resistant lines have a slightly different protein which does not bind. The immediate consequences of toxin binding are not clear, but this work has been till now the only reported case of a specific receptor for a phyto-

toxin involved in pathogenesis. Now, Steele *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **73**, 2245; 1976) report the specific binding of another phytotoxin (tentoxin from *Alternaria tenuis*) to a receptor protein in susceptible hosts.

A. tenuis is a widespread weak parasite which causes near-saprophytic infections of grain, fruit and senescent tissues generally. It does, however, cause a very distinctive seedling blight of some species, in which the cotyledons become severely chlorotic and the fungus invades the damaged seedling. This chlorosis can be exactly reproduced by treatment with tentoxin, a cyclic tetrapeptide, and it seems that the fungus is dependent on the action of the toxin for successful infection.

Steele *et al.* have now shown that tentoxin shows specificity in three respects. When added to isolated chloroplasts of a toxin-sensitive species such as lettuce, it inhibits coupled electron transport. When added to purified coupling factor 1 (CF₁, a chloroplast ATPase directly involved in photophosphorylation), tentoxin inhibits the ATPase activity. If synthetic tritiated tentoxin is added to CF_1 in a continuous ultrafiltration system, the protein can be shown to have approximately one binding site per molecule for tentoxin, with an affinity constant of $2 \times 10^8 \, M^{-1}$. Comparable tests on an insensitive species (radish) showed only slight inhibition of photophosphorylation, no inhibition of ATPase activity, and an affinity constant less than $10^4 \, M^{-1}$. Other sensitive and insensitive species fitted the same pattern with respect to inhibition of photophosphorylation. It would seem, therefore, that the CF_1 of sensitive species acts as a tentoxin receptor and that toxin-binding leads to inhibition of photophosphorylation. The CF_1 of sensitive species binds poorly and is not inhibited. These results are of great significance, first because of the specificity of the inhibition and binding, and second because the binding may in itself explain the mechanism of toxicity of tentoxin.

There are, however, certain aspects that remain to be analysed. The relation of toxin specificity to host specificity is complicated by the wide host range of the fungus and the different diseases that are caused. Toxin specificity may be presumed to relate only to the specific ability to cause a certain type of disease, that is seedling chlorosis. Certain plants, such as corn, show sensitivity of isolated chloroplasts but not of intact leaves, so that other factors may operate to cause insensitivity. In addition, the symptoms of chlorosis are most strikingly seen in seedlings with developing chloroplasts. The details of the causal relationship between inhibition of photophosphorylation and

this chlorosis are not yet established. Nevertheless, tentoxin could clearly become the first disease toxin for which the molecular basis of both specificity and toxicity can be explained. □

Coming to terms with the noisy retina

from Jonathan Ashmore

An international symposium on Photoreception was held at the Royal Society on September 2 and 3, 1976. Sponsored by the Rank Prize Funds, the symposium was organised by P. Fatt and H. B. Barlow.

RETINAL physiology has come to possess a decided flavour of engineering. Touching on problems close to the heart of any communications engineer, the mechanisms used by cells of the retina to transduce light signals in the presence of intrinsic noise were a recurrent theme at this meeting.

There now exist a number of complementary studies on the first stages of visual excitation, from the absorption of a photon by the photoreceptor pigment molecules to its transduction manifested as a change in membrane potential of the cell. There is still no evidence directly in conflict with the 'Calcium Hypothesis' advanced some years ago by W. Hagins and coworkers, (*A. Rev. Biophys. Bioeng.*, **1**, 131; 1972), which postulates that in rods calcium is released by light from the intradiskal space to diffuse intracellularly and close ionic channels on the cell membrane. Equally, there is no direct evidence supporting the idea, but Hagins and S. Yoshikami (National Institutes of Health, Bethesda), however, think that calcium is still the best bet for the intracellular transmitter. At this meeting they reported experiments intended to change the intracellular ionic environment in rat rods by fusing vesicles containing chelating agents with the cell wall. Model calculations suggest that calcium is the only ion with a sufficiently high affinity in these experiments to account for the observed changes in the rods' electrical photoresponse. Direct intracellular injection experiments in the toad rod system were reported by L. H. Pinto (Purdue University), J. E. Brown and J. A. Coles (Vanderbilt University), but again produced no evidence contradicting Hagins' story.

More than half the symposium was given over to the interactions between receptors and other cells of the retina. Since the initial indirect evidence 18 months ago by G. L. Fain that toad rod receptors are coupled (*Science*, **180**, 1178; 1975), the demonstration of inter-receptor coupling in various species has become almost a minor cottage industry. W. G. Owen and D. R. Copenhagen (University of California, San Francisco) discussed double impalement experiments with microelectrodes, showing conclusively that the coupling between rods in the snapping turtle is electrical, probably by way of the telodendria extending from the pedicles, (see *J. Physiol.*, **259**, 251; 1976). The effect of this coupling is to attenuate the signal from a singly illuminated rod to 10–20 times that produced when all the receptors are illuminated. One function for the coupling, at least in the peripheral retina, would be to improve the signal-to-noise ratio for dim diffuse lights, which would be traded off against the loss in visual acuity caused by coarsening the receptor mosaic.

Intracellularly recorded noise in turtle cones, probably produced by the opening and closing of ionic channels, has been used by T. D. Lamb and E. J. Simon (University of Cambridge) to show that in this animal the cones are electrically coupled. Quantitative measurements of the noise lead them to conclude that in these cells one photon can close one ionic channel, whereas in the rod system, as E. A. Schwartz (Harvard Medical School) reported using the same power spectrum methods, a figure closer to one photon controlling 300 channels may be more in order.

A nice bridge between electrophysiology and behavioural studies was made by G. L. Fain (Jules Stein Institute, UCLA). Using data from the behaviourally determined increment threshold curve for turtle and comparing this with the intracellularly determined light sensitivity, he estimates that a 5–10 μV signal is required in red cones for a behavioural response. This figure is below the cone noise level, although many parallel pathways exist in the retina for output. The properties of some of these retinal pathways have been mapped by D. A. Baylor and R. Fettiplace (Stanford University) by injecting current from a micropipette into cones and recording the ganglion cell response. They suggest that the pathways studied in the cone system may afford some signal-to-noise improvement by functioning as a bandpass filter; in the rod system at threshold where the problem becomes more acute a similar characteristic could be present.

The ionic mechanisms involved in

synaptic transmission have proved difficult to disentangle since usually more than one cell type meets the receptor at synaptic contact. At the synapse between receptor and depolarising bipolar cells, J-I. Toyoda (Kawasaki University) describing experiments to pass current trans-retinally produced evidence that at least two postsynaptic ionic channels are transmitter modulated. The hyperpolarising bipolar cells still conform to the original suggestion that light produces a permeability decrease to a single ion species.

A method to decouple the horizontal cells from their putative role in the feedback loop at the receptor triad synapse would be very helpful here, but failing this an interesting technique was reported by Yù. A. Trifonov and A. L. Byzov (Moscow University) to study the electrical properties of the horizontal cell membrane. Because of extensive electrical coupling between these cells, microelectrode studies of the cell membrane are not feasible; the method used here is a modification of Kramer's *'Winkel rinne'*, and results suggest cell membrane possesses anomalous rectification properties. Whether this will yield further information on the receptor synapse remains to be seen.

We may now be in a position to localise the cellular origins of the 'noise' treated in the psychophysical literature as the ultimate determinant of visual discrimination. Stressing this point, however, H. B. Barlow (University of Cambridge) tentatively suggested from experiments using random dot patterns that the factors which limit the quantum efficiency of seeing determined from performance tests may not arise in the retina at all but from "nasty central processes going on". Central limitations to quantum efficiency can only revise estimates of retinal efficiency upwards. ☐

Pesticides and the environment

by Mary Lindley

A symposium on the ecological effects of pesticides, sponsored by the Institute of Biology and the Linnean Society was held in London on September 23–24. The proceedings will be published by Academic Press.

PESTICIDES are not likely to be abandoned to the accompaniment of cries of ecological doom, although they

clearly can be misused and have caused death and destruction in some cases. DDT and its successors have wrought so much good in controlling disease and increasing crop productivity that they must continue to be used, albeit in moderation and with constant efforts to find alternatives. This was the message of the symposium, during which very few speakers discussed directly the ecological effects of pesticides.

According to H. C. Gough (Ministry of Agriculture, Fisheries and Food, London), the benefits of pesticides used correctly in agriculture far outweigh their hazards. Their use has greatly reduced losses of many crops from pests, diseases and weeds. Without pesticides, he said, production would decline and costs would increase. Unnecessary use occurs, however, and there is a continuing need to ensure that hazards are minimised in the application of pesticides.

A particularly hopeful development in crop protection from the ecological point of view is selectivity. I. J. Graham-Bryce (Rothamsted Experimental Station, Harpenden) cited in particular the pyrethroids, which are potent insecticides, through their actions as nerve poisons, but not harmful to mammals. Another target for selective pesticides is the endocrine system of insects; juvenile hormone analogues and anti-juvenile hormone compounds hold promise.

The control of pests and diseases in forests presents a greater dilemma than when agricultural crops are concerned. Pesticides are in any case more likely to upset biological equilibria in perennial than in annual plant environments and the multipurpose nature of many forests adds to the complications, as M. J. Way (Imperial College Field Station, Silwood Park, Ascot) explained. He pointed out that the balance between species in forests may indeed be maintained by pests: for example, without spruce budworm some forests would be monocultures of spruce. But on the whole, pesticides are used less in forestry than in other major production systems.

The disastrous ecological consequences of the use of herbicides to defoliate large tracts of forest in Vietnam during the recent war were described by Dr A. H. Westing (Stockholm International Peace Research Institute). Severe destruction of habitats was caused in more than 50,000 hectares of upland forest and in 150,000 hectares of mangrove forest during the American programme of spraying with 2,4-dichlorophenoxyacetic acid and 2,4.5-trichlorophenoxyacetic acid. According to Westing, the damage will be long lasting and has effectively deprived Vietnam of a proportion

of its forests.

The difficulties of monitoring the ecological effects of pesticides, particularly in developing countries, were made very clear by W. E. Kershaw and M. Pugh Thomas (University of Salford). They have been studying the effects of insecticides used to control the blackfly vector *Simulium damnosum* in the World Health Organization Onchocerciasis (river blindness) Control Programme. They have found that investigations of the biological side effects of pesticides on fast flowing rivers in Africa are expensive, tedious and hazardous. So far they have no evidence that fish have been affected, while the data obtained for invertebrates are very hard to interpret. Pugh Thomas believes that to allow for seasonal effects it will be necessary to compare data for successive years before a clear picture is likely to emerge.

The problems involved in predicting how pesticides will affect the environment were underlined by F. Moriarty (Institute of Terrestrial Ecology, Monks Wood Experimental Station, Huntingdon). Direct field trials are difficult, and the various indirect approaches used have disadvantages. But he said two tentative assumptions are possible: organisms have little effect on the amounts of pesticide in the physical environment, and if individual organisms are affected adversely, then ecological effects are imminent or already happening.

The prospects for wildlife, according to N. W. Moore (Nature Conservancy Council, London), depend more on the future of their habitats than on the use of pesticides. The decline in the wildlife population in Britain during the past 150 years has been due more to the destruction of habitats for land development than to the effects of pesticides. He pointed out, however, that treatment with pesticides can be locally damaging, and it will be increasingly important to ensure that pesticides do not spread away from the crops which they are protecting, for example by drift or in effluent. He said that the future of wildlife in the farmed countryside will depend on the conservation of areas of unfarmed habitat, where pesticides cannot reach.

Discussing future prospects for man, K. Mellanby (Institute of Terrestrial Ecology, Monks Wood Experimental Station) said that although in an ideal world pesticides would be unnecessary, they will continue to be used, and with proper precautions and controls, they can do their job while man's environment continues to be improved. He said that the dangers inherent in the use of pesticides are generally accepted and there has often been public overreaction to them. ☐

Astronomically-oriented markings on Stonehenge

Richard F. Brinckerhoff

Science Department, Phillips Exeter Academy, Exeter, New Hampshire 03833

In view of the years of careful study that have been devoted to Stonehenge it may seem unlikely that any more information could be extracted from the monument, or at least from that part of it above ground. During the past two years, however, further markings have come to light that are, at least, interesting, and possibly important. These markings are a series of at least 11 pits on the upper surfaces of the three contiguous lintels (130, 101 and 102) that span the well-known line of sight from the centre of the sarsen circle north-eastward towards the heel stone. For an observer diametrically across the circle, 9 of these pits identify directions of the rising moon at significant points in its 18.6-yr cycle.

THE lintel-top surfaces of Stonehenge maintain a true level with the horizon to within a few inches in spite of the fact that within the sarsen circle the ground level drops down towards the north-east by ~ 1.5 feet. If the sole purpose of the lintels was architectural, it is hard to see why such a small correction-to-level would have justified the effort; its architectural effect would be imperceptible. But as a walkway for observing horizon events such a correction would make sense. Moreover, the diminutive, upright stone 11 in the south-east quadrant could then be explained as a midway support to a stair which, forking to left and right at its top, gave access to the lintel-top walkway.

This hypothesis suggests the possible existence of astronomically oriented markings on the lintel surfaces, but nowhere in the Photographic Library of the Department of the Environment was there a close-up picture of any of the nine lintels now in place. Direct inspection was therefore necessary.

In July of 1974 with the permission of the Department of the Environment and the help of Mr Woodhouse, the head custodian, a ladder was provided and all nine lintels

inspected. Only lintels 130, 101, and 102 (the three contiguous ones in the north-east quadrant of the sarsen circle) showed promising markings[1]. In 1975, again with permission and help, a series of measurements, photographs, and plasticene moulds were carefully made. Figure 1 shows the surface of the three lintels made by piecing together a sequence of photographs made approximately every 2 feet along the lintel tops from a height of 5.5 feet. They were taken with the Sun low in the west, at about 1800 on June 13, 1975, shadowing the rock surface. The measuring stick is 2 feet long.

Pits

The significant markings are a series of pits, some of which in the photograph contain vertical wands used for locating them precisely from the ground. The pits are identified by numbers in Fig. 2, which is made from a tracing of a photograph, originally 2.5 feet long.

Pit 1, the largest, is almost circular both in plan and in section, ~ 10 inch across and 3 inch deep. (The numbers here given are only approximate because of the irregular surface of the lintels, and the fact that not all the pits have clearly defined edges.) Pits 2, 3 and 4 are much smaller, 1.5–2 inch in diameter, quite round but irregular in depth. Pit 5 is round, 3 inch in diameter and about as deep. Near it is a pit, 6, that may be more significant though it is of irregular shape, an uneven 3×1.5 inch in plan and up to ~2 inch deep. Pits 7 and 8 command attention because of their location almost directly over the sight line from the sarsen circle centre to the heel stone. They are both approximately 4 inch in diameter and depth with regularly rounded bottoms. Finally, pits 9, 10 and 11 are shallow, smaller, and not quite so regular in shape. Pits 1 to 8 (excluding 6) are so regular in shape as to be plausibly man-made; the others together with several smaller markings command less confidence, but all of them stand out sharply in appearance from the uneven weather-worn surface of the lintels. Indeed, pits 1, 7 and 8 can be detected in some low level air views already in print.

Fig. 1 Composite photograph of lintel tops from a height of ~ 5.5 feet showing pits. The measuring stick is 2 feet long.
Fig. 2 Identification of pits in Fig. 1 and the alignments through them. The directions shown are approximate.

Alignments

To pursue the possibility that the pits are man-made it is necessary to locate them accurately on the overall plan of the monument. It was found by projecting Hawkins's 1965 photogrammetric air survey map[2] on to an enlarged drawing of the Thoms' more recent survey[3] that the two agree precisely in all essentials. We used the air survey, except for the replacement of the three lintels by a reduced rendering of Fig. 2.

Nine of the eleven pits identify significant directions for an observer posted on the now non-existent lintel top diametrically across the sarsen circle at P (Fig. 3). P falls on the centre of sarsen upright 15.

When the lintel-top pits are plotted on the air survey map it is found that a line through pit 1 to the northernmost point of moonrise and a line through pits 9 and 10 to the northernmost (midsummer) sunrise intersect on the south-western side of the sarsen circle at P. P is defined by the intersection of these two sight lines.

Moreover, as viewed from P, pits 2 and 4 point very nearly but not precisely to the northernmost of the four A holes (A1). Similarly, a line from P through pit 5 (not drawn in Fig. 3) points very nearly to A2. A line from P through the Aubrey hole centre shown as a dot (but not through the sarsen circle centre shown as ✕) passes through pit 6 and very close to the midpoint of the A holes between A2 and A3. And the conspicuous pits 7 and 8 over the central archway point very nearly to A4. All of these lines miss the A holes by the same amount and in the same direction (eastward), a matter discussed further below. Only pits 3 and 11 elude an obvious pattern. So simple a pattern

fitted so precisely by such a large majority of the pits is additional evidence that the pits (or at least nine of them) are man-made.

From point P none of the pits aligns with the rising point of Venus or of any of the 20 brightest stars except, implausibly, Pollux after corrections are made to the year 2000 BC for the precession of the pole. Nor do any of the pits seen from the sarsen circle centre or the Aubrey hole centre align with any significant sunrise or moonrise points or with Venus or the brightest stars.

A shift in the observation point

There is a strong intuitive appeal in the idea that the viewing point should not be at P but at a point ~5 feet westward so that the observer would be on what the Thoms[3] have identified as the axis of symmetry of the monument. There he would have a clear view under the lintel of the great trilithon whose bottom surface would be 5.5–6 feet above his footing atop the sarsen circle. The angular spread of the alignments (pit 1 to pits 9, 10) is 10°, too great to be seen through the trilithon from one spot, but as the observer walked north-westward from P along the lintel tops he would see the pits revealed progressively through the arch as he moved. Pit 1 would come into view (azimuth 42.3°) in approximately the direction of the northernmost moonrise (azimuth 40.5°), and pits 7 and 8 would be seen almost (but not quite) in line over the sarsen circle centre, with the centre of the heel stone at 51.7°; the azimuth of the midsummer sunrise is 50.7°. These are unsupportably large discrepancies. Moreover, viewed through the trilithons in this way pits 2–6 and 9–11 have no obvious significance.

Fig. 3 The alignments through the lintel-top pits to outlying A holes and horizon points.
Fig. 4 Close-up of some of the pits showing how they may have been used to support wands as sights.

Also, when vertical wands are erected in pits 2, 4 and 7, 8 (Fig. 4) they appear precisely aligned only as seen from within ~ 1 foot from P (Fig. 5) and not through the trilithon arch, 5 feet from P. Finally, since the axis of the monument is aimed very nearly at midsummer sunrise, it can scarcely be aimed simultaneously at, or be symmetrical with, moonrise points all to the N. On the whole, the alignments radiating from P are impressively accurate.

Orientation

With the help of plumb lines pit 1 was located at ground level on the monument plan to within 4″, and its azimuth was found to be 40.5°. Using the procedure given in ref. 4 the first gleam of the northernmost moonrise ($\delta = +29.1°$) on the horizon of Stonehenge is found to have an azimuth of 40.7°.

Similarly, the ground level location of pits 9 and 10 identify an azimuth of 51.0° from P, whereas the first gleam of midsummer sunrise ($\delta = +23.9°$) seen over the heel stone from the sarsen circle centre has an azimuth of 50.1°.

With pits 1, 9 and 10 thus located on the plan, a tracing of the lintel-top photograph (Fig. 2) was reduced in size until pits 1, 9 and 10 on the photograph registered accurately with the plan. The lintel-top tracing was then drawn, thus locating accurately all the intervening pits. So located, the pits identify the lines toward the A holes (Fig. 3) (See Table 1 for azimuths).

The accuracy with which the sunrise and moonrise lines are located on the map is limited by uncertainties of an inch or two in the restoration of the three lintels in 1919–20 and the fact that location of the pits on the map are accurate to only ~ ±4 inch and that angles measured in Fig. 3 are no better than ±0.25°. Together these errors result in an uncertainty in the location of P of ~ 1.0 foot.

Accuracy

In an effort to judge the accuracy with which the lintel-top pits align with the A holes, a camera was set up approximately at point P. In Fig. 5 beneath the right-hand lintel top wands in pits 7 and 8 is an arrow pointing to a post erected in the centre of hole A4, almost exactly three sarsen circle diameters from the camera. Although pit A1 is obscured it can be located in effect by simple geometry 20.4 feet left of A4, which agrees with the distance actually measured on the ground. Measurements on the photograph show that to make the pits align with the A

holes, the camera would have to move 1.0 foot eastward to be centred on P and then an additional 1.4 feet eastward beyond P. This is appreciably more than the ±1.0-foot uncertainty, inherent in the original map location of P. Thus, in spite of their identity of spacing, the set of sarsen circle alignments appears to be shifted slightly to eastward of the set of A-hole alignments. It looks as if the builders had come up with two slightly different solutions to the same observational problem. For an explanation of this mismatch we must first examine the consequences of the fact that the A holes and the sarsen circle lintel pits were in use at two widely different times.

Stonehenge I

The A holes 3 feet in diameter, were only 4 feet deep, much too shallow to support the 28-foot posts required for a man standing on the lintels to use them for sighting. Moreover, post hole A1 was not only filled in but was entirely buried by the bank created by the building of Stonehenge II. Together these facts point to the use of the A-hole posts as sights by ground-level observers before the construction of Stonehenge II.

At that early time, when there was no sarsen circle, it seems likely that the observers were stationed at the centre of the Aubrey hole circle rather than at P. The reason for this is simply that from the centre of the Aubrey hole circle the four A-hole posts (centre line azimuth 45.5°) would have been centred between the line to the heel stone (50.7°) marking the northernmost sunrise, and the line to the northernmost moonrise (40.5°). Posts on the A holes would then mark the 18.6-yr swing of the moon during intermediate years. When the Moon rose through the first opening (A4–A3) of the four posts, it was just one quarter of the way in time from rising on the line of midsummer sunrise and rising at its northerly extreme; when it rose through the middle opening it was just one third of the way to its maximum, and when it rose behind A1 it was exactly halfway.

Although the precise date of the maximum would be impossible to identify accurately, just as for the Sun, since, close to the maximum, the change in azimuth with time is too small to observe, the date could nonetheless be inferred quite accurately in retrospect as lying halfway in time between the northbound and the southbound traverses of any one of the three A-hole openings. After one or two such pairs of traverses (18.6 yr apart) the observers could confidently predict the proper date for ritual celebrations of the maximum.

**Fig. 5** Ground-level view of the wands in Fig. 4 from a point 1 foot west of the presumed position of P.

Table 1 Orientation data of the pits on Stonehenge lintels

Alignment from P through pit:	Towards	Azimuth E of N±0.2°	Vertical error, D°, for		
			First gleam	Centred on horizon	Tangent on skyline
1	Northernmost moon $\delta = +29.1°, A = 40.5°$	40.5	−0.09	−0.39	−1.67
2, 4	A1	43.5			
3		43.6		> 1.5	
5	A2	44.5		for both Sun and Moon	
6	Mid-A and Aubrey centre	45.5			
7, 8	A4	47.5			
9. 10	Midsummer sunrise $\delta = +23.9°, A = 50.7°$	50.7	+0.63	+0.40	+0.10
11	Midsummer sunrise	51.2	+0.92	+0.68	+0.45
Through centre of great trilithon to pit:		**Azimuth E of N ± 0.6°***			
1	Northernmost moon $\delta = +29.1°, A = 40.5°$	42.3	+0.75	+0.52	+0.29
2, 4		45.8		> 1.5°	
3		47.5		for both Sun and Moon	
5		47.8			
6	Midsummer sunrise	48.5	−0.53		
7	Midsummer sunrise	51.7	+1.18	+0.94	+0.82
8	Midsummer sunrise $\delta = +23.9°, A = 50.7°$	51.8	+1.23	+0.99	+0.87
9, 10		56.0			
11		56.5		> 1.5°	

*Error is higher than from P because of uncertainty concerning midpoint of trilithon arch.

The end came when the Beaker invaders, bringing with them a new culture, realigned the axis by the construction of Stonehenge II, evidently focusing on the midsummer sunrise and burying the A holes. The Moon seems to have been replaced by the Sun in the culture of the newcomers.

Stonehenge III

Centuries after the A holes had been obliterated the sarsen circle was erected, its axis also oriented to the midsummer sunrise, as was Stonehenge II before it. Then or later, wands supported upright in the new lintel-top pits must have once more identified the old alignments for observers at P, now 16 feet up off the ground to avoid being blocked by the new sarsen circle and the old bluestone circle uprights.

In their paper[5] on Stonehenge as a possible lunar observatory the Thoms discuss the improvement in visibility of foresights on distant hills made possible by raising the level of the observer above the ground level. Is this consideration one of the determinants of the height of the lintel-top walkway? No one has ever explained convincingly why it had to be 16 feet high. Do our pits identify distant foresights visible only to a lintel-top observer? The Thoms mention C. A. Newham's[6] observation that if Stonehenge were raised only a few feet, distant hills would become visible to the northeast. Certainly a lintel-top platform creates new possibilities for observations similar to those discussed by the Thoms[3,5] and Newham[6] as well as raising new problems.

Difficulties

One problem that has a plausible solution is the mismatch between the A-hole alignments and the lintel-top pits alluded to earlier and illustrated (and exaggerated) in Fig. 5. Their alignments shifted slightly eastward, the lintel-top pits appear to attest to the slow eastward drift of the extreme declinations of the Sun and Moon caused by the slowly changing obliquity of the ecliptic. For example, in 3000 BC the maximum declination of the moon was 29.18°, and in 2000 BC it was 29.08° (ref. 7). As a consequence the northernmost rising point of the Moon shifted 0.21° eastward. But a 0.21° shift eastward corresponds to the observer moving 0.5 feet eastward from the presently plotted position of P. This, together with the 1.0-foot uncertainty in P's

location amounts to 1.5 feet, a shift in P sufficient to bring the two sets of alignments into precise coincidence, assuming the maximum possible error in the original location of P. (A 1.4-foot shift in the map position was required.) In principle, if the position of P were known exactly and our interpretation is correct, the angular difference between the two sets of alignments would lead to a knowledge of the time difference between Stonehenge I and the creation of the lintel-top pits on Stonehenge III.

A much more serious problem remains. When Stonehenge III had been completed stone 55 of the great central trilithon, now fallen, would have completely blocked the view of the lintel-top observer at P. Perhaps the trilithon was erected only after the sarsen circle and the pits had been in use for some time, but this seems unlikely since it would be almost impossible to erect the trilithon after the sarsen circle had been completed. Nor do our pits seem to identify any useful alignments to an observer looking through the trilithon arch.

Speculations

Perhaps in the troubled times towards the end of the use of Stonehenge as an observatory, the trilithon was pushed over —to make way for the re-establishment of the lunar alignments—and has lain broken in its present position ever since. If this event is archaeologically dubious, it at least has the merit of accounting for most of the pits.

More plausibly, perhaps, a 4-foot high wooden platform may have been erected at P to permit viewing over the top of the trilithon.

In conclusion, although we lack an exact explanation of how sightings could have been made or why the alignments were off-axis, these results nevertheless have significance in our understanding of the astronomical aspects of Stonehenge. The original theory that the site was an observatory accurate to the width of the archways is now augmented with alignments accurate to within a few inches.

$^{207}Pb/^{206}Pb$ whole-rock age of gneisses from the Kangerdlugssuaq area, eastern Greenland

W. P. Leeman & E. J. Dasch

Department of Geology, Oregon State University, Corvallis, Oregon 97331

M. A. Kays

Department of Geology, University of Oregon, Eugene, Oregon 97403

We present here a brief description of geological relations and results of lead isotopic analyses of eight whole-rock samples of Precambrian gneiss from an area near the Skaergard Intrusion in the Kangerdlugssuaq region of eastern Greenland.

EXCEPT for Wager's[1] regional reconnaissance studies, there have been few published details of the Precambrian geology of Eastern Greenland. Berthelson and Noe-Nygaard[2] have suggested that basement rocks of the Kangerdlugssuaq region belong to the Kenoran tectonic division (that is, rocks of pre-Ketilidian, or more than about 1,800 Myr old) of the Canadian–Greenlandic Shield. A limited number of K–Ar ages[3-4], ranging from 2,700 to 1,600 Myr BP, have been reported for Kangerdlugssuaq area gneisses, but interpretations of these data are suspect because of widespread Tertiary igneous activity in the area[5-7]. Our field studies have indicated a complex history for the gneisses, which is summarised in Table 1.

Interlayered mafic and felsic gneisses represent the earliest recognisable unit in the area (event 1, Table 1). These interlayered gneisses are interpreted as dominantly metaigneous rocks, but a small amount of intercalated metasedimentary material is locally present. Strong banding is developed in the gneisses primarily among quartzofeldspathic units. Distinctive mafic bands a few centimetres to several metres thick are also present. This gneiss suite has characteristics similar to those described for gneisses in western Greenland and equivalent gneisses elsewhere in the Archean Craton of the north Atlantic region[8-10]. In the Kangerdlugssuaq area mafic gneisses vary from nearly pure hornblendite to plagioclase-rich amphibolite. Locally, this lithology is abundant, forming mappable units of mafic gneiss up to 200 m thick. More commonly, the mafic gneisses have been pulled apart, rotated, and fragmented within a matrix of quartzofeldspathic gneiss, giving the impression that large mafic gneiss xenoliths have been rafted and deformed by later emplaced felsic gneisses. This impression may, however, be an oversimplification in as much as the mafic gneiss blocks are in places definitely interlayered with quartzofeldspathic to biotitic gneisses. Thus, it seems probable that some blocks of felsic gneiss also occur as xenolithic rafts.

Metasedimentary rocks which occur among the early gneisses are dominantly felsic gneisses with variable amounts of plagioclase, alkali feldspar, and quartz and accessory biotite and hornblende. With increasing quartz content these gneisses grade to sugary textured quartzites; with increasing biotite they become schistose and some contain garnet porphyroblasts in a fine-grained quartz and feldspar matrix. Hornblende-rich and/or biotite-rich layers are also present in the felsic metasedimentary gneisses. It

is possible that these metasediments are remnants of a once extensive supracrustal sequence that was incorporated into the metaigneous suite either as conformable sedimentary beds in a volcanic sequence or as infolded units. Alternatively, they may reflect conformable tectonic interleaving, as inferred for the Malene supracrustals within the Amitsoq gneisses in Godthabsfjord[8].

Textural and structural relationships within the later sequence of metaigneous rocks (event 2, Table 1) suggest that there were several intrusive pulses. The early intrusive rocks are commonly granite or trondhjemitic. Because of their similarity in composition and texture to felsic rocks of the earlier interlayered gneisses, contacts between the two units are discernable only in a few favourable localities. Discordant contacts are most clearly displayed where rafted blocks of agmatised interlayered mafic–felsic gneiss are enclosed by intrusive granitic or trondhjemitic gneisses. Locally, the metaigneous gneisses display pronounced coarsening, largely conformable with foliation, and associated with the occurrence of pegmatitic patches and lenses; in extreme cases these zones become essentially migmatitic. It is not clear whether the coarsening effect and migmitisation are related to a separate intrusive pulse. In some areas granitic rocks occur with little internal fabric; these bodies are apparently the latest recognisable intrusions in the area.

The grade of metamorphism throughout the entire gneiss sequence is amphibolite facies, except in areas where migmatisation is most widespread and/or intrusive rocks are more abundant. There, pyroxenes are present rather than biotite and hornblende in the felsic gneisses, and the grade of metamorphism reaches granulite facies. The higher metamorphic grade may be a relict of the cooling history of the intrusive bodies.

Table 1 Brief outline of geological events recorded in the Kangerdlugssuaq region, eastern Greenland

1 Accumulation of interbedded volcanic and minor sedimentary units. Metamorphism and deformation produced interlayered mafic and felsic gneisses, strongly folded isoclinally.

2 *a*, Intrusion of granitic and trondhjemitic plutons accompanied, or closely followed by, strong deformation and recrystallisation which produced disharmonic folding of the interlayered mafic and felsic gneisses.
   b, Igneous activity was apparently protracted and in later stages produced mafic as well as potash-rich granitic plutons and pegmatites.

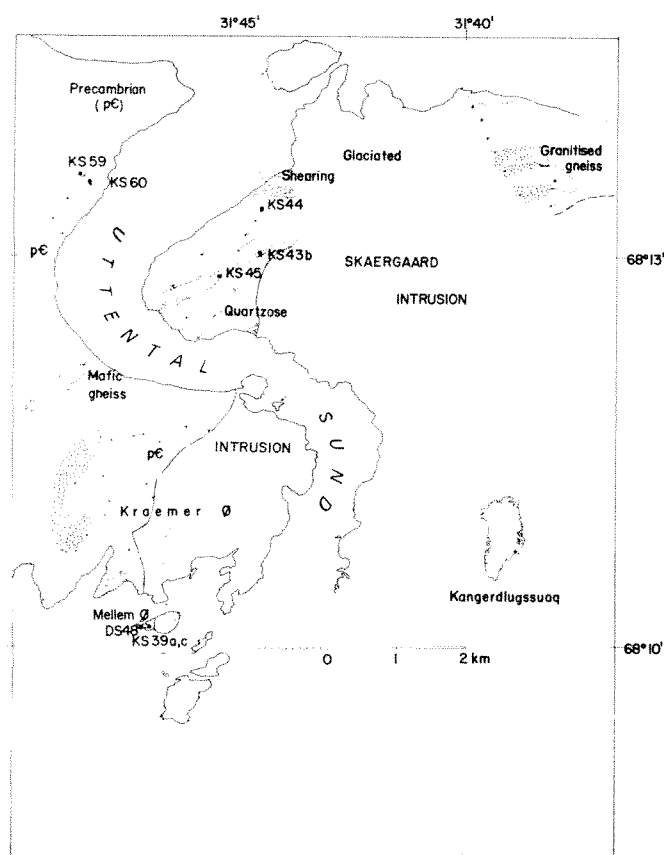
3 Subsequent to, and perhaps closely following, intrusive activity all the layered gneisses and plutonic bodies were folded and metamorphosed. This was followed, possibly at the end of folding, by pervasive shearing and by partial retrogressive recrystallisation.


Fig. 1 Geological sketch map of the Kangerdlugssuaq area, showing locations of analysed samples.

Deformation of the gneisses is intense, with at least three major episodes of folding accompanying the several intrusive pulses. In the Kangerdluqssuaq area pervasive shearing (event 3, Table 1) has affected the continuity of earlier fold forms. Shearing was also accompanied by partial retrogressive recrystallisation. In areas of very intense shearing recrystallisation was more complete, pegmatitic gneisses were deformed to augen gneisses, and finer-grained rocks were mylonitised.

Lead isotope results

Samples from each of the gneiss sequences were selected for lead isotopic analysis; sample localities are shown in Fig. 1. Whole-rock powders were dissolved with HF and $HClO_4$, and lead was extracted using an HBr cation exchange procedure. Full procedural blanks amounted to 10–15 ng for 1-g samples (that is, less than 1% of the total quantity of Pb processed for any sample). Isotopic analyses were made on a 12-inch solid source mass spectrometer, using a silica gel–H_3PO_4 matrix. All analyses have been corrected for mass fractionation in the spectrometer by intercomparison with the NBS common lead standard (SRM-981). Corrected isotopic ratios are believed to be accurate to better than 0.15% of absolute values.

The isotopic analyses (Table 2) for the Kangerdlugssuaq gneisses are shown in a $^{207}Pb/^{204}Pb–^{206}Pb/^{204}Pb$ diagram in Fig. 2. If the inconsistent sample KS-60 (cataclasised augen gneiss) is excluded, the remaining seven samples lie within analytical uncertainty of an isochron with a slope of 0.220 ± 0.003 (1σ), corresponding to an age of $2,980 \pm 20$ (1σ) Myr BP (see ref. 11). Such a close fit to the Pb–Pb isochron suggests that these gneisses were derived from a source region that was homogeneous with respect to U/Pb during approximately single-stage evolution from the time of formation of the Earth to the isochron date. Geochemical differentiation at the latter time produced severe fractionation of U/Pb as well as isotopic homogenisation of Pb (that is, igneous parental material for

the gneisses acquired the mean isotopic composition of their source region at the isochron date, but had variable U/Pb). It is not clear whether isotopic rehomogenisation took place during the final metamorphism of gneisses emplaced over a significant period of time, or whether the gneisses were derived from the same homogeneous source over a relatively short period of time just before the culminating metamorphism. In the first case, the isochron date represents event 3 in Table 1, and a significant history of unknown duration is implied for the earlier events. In the second case, the isochron date may reflect the age of igneous material that was parental to the gneiss complex. But because the rocks associated with each sequence of events conform to the isochron, the latter possibility requires that the culminating metamorphism closely followed (within a few 10^7 yr) emplacement of the various parental rocks. We cannot yet resolve this problem, but because of the complex geological history recorded by the Kangerdlugssuaq rocks the first possibility seems more likely. Considering the wide spread in $^{206}Pb/^{204}Pb$ obtained for our samples, and the small residuals obtained in the isochron regression, it seems improbable that further whole-rock Pb isotope analyses of Kangerdlugssuaq gneisses will reveal ages older than about 3.0×10^9 yr.

Sample KS-60 may be inconsistent with the lead-isotope systematics of the other samples because of uranium loss (relative to lead) subsequent to intense shearing of this rock. But recent loss of uranium (for example during early Tertiary igneous activity or post-glacial uplift in the area) would not account for the comparatively low $^{207}Pb/^{204}Pb$ ratio in KS-60. It also seems unlikely that KS-60 was not initially affected by the event which caused effective homogenisation of lead isotopic compositions in the other gneiss samples (as seems required from the excellent fit of these samples to the $^{207}Pb/^{204}Pb–^{206}Pb/^{204}Pb$ isochron). Therefore, we think it likely that uranium loss occurred during, or shortly following, the shearing of KS-60.

Kangerdlugssuaq gneisses

A single-stage $^{238}U/^{204}Pb$ (μ_0) of 8.1 is indicated for the source materials of the Kangerdlugssuaq gneisses. This value of μ_0 corresponds to a lead isotope growth curve which intersects our $^{207}Pb/^{204}Pb–^{206}Pb/^{204}Pb$ isochron at 2,980 Myr and 0 Myr, based on values for primordial lead isotope ratios and decay constants given in ref. 11. This comparatively low value of μ_0 is compatible with a mantle or lower crust source region for igneous precursors to the gneisses, because upper crustal rocks are generally enriched in U/Pb. For example, such enrichment in U/Pb is inferred for the Isua supracrustal rocks which yield a μ_0 value of 8.7 (ref. 12). On the other hand, profound U depletion noted in many ancient infracrustal gneisses can

result in present-day-unradiogenic Pb isotopic compositions. For comparison, 2.8×10^9 yr-old granulite facies rocks from south-western Greenland yield a μ_o value of 7.5 using the same decay constants[13]. The lower value of μ_o obtained for these granulite gneisses is in accord with the observation that U depletion commonly becomes more pronounced as metamorphic grade increases[14]. The 3.7×10^9 yr-old Amîtsoq gneisses of western Greenland also yield lower values of μ_o (about 7.6 to 7.7) and, in addition, contain Pb that is much less radiogenic ($^{206}Pb/^{204}Pb$ ranges from 11.5 to 14.9)[15,16] than the Kangerdlugssuaq gneisses. Consequently, it is unlikely that the Kangerdlugssuaq gneisses could represent metamorphosed parent material equivalent in composition to the Amîtsoq gneisses. Our work does not preclude the existence in the Kangerdlugssuaq area of older material with a composition different from that of the Amîtsoq gneisses. The Vikan migmatitic gneisses in northern Norway yield a Pb–Pb whole-rock isochron age of about 3.5×10^9 yr, and a value of μ_o of 8.9 (using the decay constants given in ref. 11)[17]. The range of $^{206}Pb/^{204}Pb$ values in these gneisses (14.8 to 21.2) is within the range for the Kangerdlugssuaq gneisses, but the latter display lower $^{207}Pb/^{204}Pb$ ratios in accordance with their younger age. Conceivably, high-grade metamorphism of Vikan-like rocks more than 3.0×10^9 yr ago could have pro-

duced gneisses with Pb isotopic compositions like those in the Kangerdlugssuaq rocks. A discussion of the origin of the Kangerdlugssuaq gneisses will be presented elsewhere.

The approximately 3.0×10^9-yr-old metamorphism recorded in the Kangerdlugssuaq gneisses was apparently related to regional metamorphism of high amphibolite or granulite grade (depending in part upon level of exposure) that affected much of the Greenland Shield between 3.0 and 2.7×10^9 yr ago[9,13,18–22]. High-grade metamorphic rocks of similar age have been documented from the Lewisian Complex of north-western Scotland[24–27]. It has been noted that this blanket metamorphism affected supracrustal as well as infracrustal rocks, thus recording an actual rise in crustal temperature during that time[9]. The complex geological relationships recorded in the Kangerdlugssuaq gneisses, like those occurring in the Lewisian gneisses[10], suggest a more extensive history of crustal evolution that predates the $3.0–2.7 \times 10^9$-yr-old event. U–Pb zircon and Rb–Sr whole-rock analyses are in progress in an attempt to resolve earlier events and to test our interpretation that the whole-rock Pb–Pb isochron age for the Kangerdlugssuaq gneisses reflects the time of last major metamorphism in that area.

In patients with β⁰ thalassaemia from Ferrara, β globin mRNA sequences are either absent or structurally abnormal while in β⁰ thalassaemia in Catania, β globin mRNA sequences are present. In δβ thalassaemia there is a deletion of β-like globin genes, while in β⁰ Catania DNA, no β globin gene deletion is detectable.

THREE general types of β thalassaemia have been described to date: β⁺ thalassaemia, associated with the production of decreased amounts of structurally normal β globin; β⁰ thalassaemia, characterised by the absence of β globin synthesis; and δβ thalassaemia, in which synthesis of both δ and β globin is absent[1]. The defect in β globin synthesis in these syndromes can be demonstrated by measurements of globin synthesis both in whole cells and by addition of isolated mRNA to
Fig. 1 Globin synthesis in reticulocytes of β^0 Ferrara. Elution from carboxymethyl cellulose chromatography of globin prepared from cells of a patient homozygous for β^0 Ferrara (patient 2 in Fig. 4b and Table 1) which had been incubated with ^{3}H-leucine.[4] The patient had been transfused 22 d before the blood sample was obtained.

heterologous cell-free systems[2-5]. More recently, the availability of complementary DNAs (cDNAs) specific for α and β globin mRNA sequences has made it possible to quantify the α and β mRNA content of cells in these disorders[6-12]. In the β^+ thalassaemias, we and others[6,7] have shown previously, using these molecular probes, that the amounts of cytoplasmic β globin mRNA is decreased. By contrast, in β^0 thalassaemia in patients from Italy, there have been conflicting reports[8,11] either of the absence of structurally normal β mRNA sequences, or of structurally abnormal β mRNA sequences. β mRNA sequences in $\delta\beta$ thalassaemia have been shown previously to be absent[8]. We report here that in β^0 thalassaemia in patients from the Ferrara region of Italy, another distinctive genetic defect may be reflected at the mRNA level by the inability of β^0 Ferrara mRNA to hybridise fully to β cDNA. In contrast, we find significant amounts of β mRNA in β^0 Catania mRNA, which is consistent with the presence of abnormal, untranslated mRNA in some β^0 thalassaemia patients[6,11]. We also report that

Table 1 Amounts of α and β mRNA and percentage β cDNA hybridised

Source of RNA*	α/β mRNA content†	% β cDNA hybridised‡
Normal (8)§	0.9–1.36	90–96
β^+ thalassaemia (6)	4.5–14.3	82–88
$\delta\beta$ thal homozygote	0	18
β^0 Catania —1‖	2	80
—1‖	2.4	80
β^0 Ferrara —1	1.8	50
—2	1.78	54
—3	1.43	46

*6 to 16S RNA was isolated by sucrose density gradient centrifugation in all cases from peripheral blood.
†$C_0t_{\frac12}$ β cDNA/$C_0t_{\frac12}$ α cDNA. The $C_0t_{\frac12}$ is the C_0t at the midpoint between the initial and final hybridisation plateau.
‡The % of β cDNA resistant to micrococcal nuclease digestion at the final hybridisation plateau. The background without added RNA has not been subtracted.
§Number of patients studied is in parentheses.
‖Studies performed twice on the same patient.

in $\delta\beta$ thalassaemia there is a deletion of structural δ and/or β globin gene sequences; in β^+ and β^0 Catania DNA, no such deletion is detectable. These results indicate a heterogeneity of gene defects in β thalassaemia, all of which can lead to decreased or absent β globin synthesis.

The β^0 Catania patients are homozygous for β^0 thalassaemia and manifest the clinical symptoms of β thalassaemia. They range in age from 5 to 10. All of the patients have hepatosplenomegaly, abnormal red cell morphology with hypochromic, microcytic anaemia, elevated haemoglobin A_2 and F levels and require blood transfusions. The $\delta\beta$ thalassaemia homozygote is a patient who has only haemoglobin F, a mild anaemia, and thalassemic smear with hypochromic, microcytic cells[13]. The β^0 Ferrara patients have high A_2-type homozygous β thalassaemia[14]. Fibroblasts from patients with hereditary persistence of foetal haemoglobin (HPFH) and from normal patients were cultured by Dr Robert Krooth. The HPFH fibroblasts are from a patient who is homozygous for the black form of this disorder[15].

Total RNA was extracted from peripheral blood samples from which buffy coat had been removed[16]. RNA was fractionated on sucrose density gradients and the 6–16S region was used in hybridisation and biological activity studies. α and β globin cDNAs were purified as previously described[9]. The α and β globin cDNAs sediment as a relatively homogeneous 7S peak using alkaline sucrose gradient analysis. DNA was prepared essentially as described previously[17]. Hybridisation of globin cDNA with spleen, liver, fibroblast and white blood cell DNA was also performed as previously described[9].
Fig. 2 Hybridisation of α and β cDNA with normal (a) and homozygous $\delta\beta$ thalassaemia RNA (b). Between 2,000 and 2,500 c.p.m. of α or β cDNA were hybridised to 5×10^{-6} to 1.2×10^{-2} µg of normal 6 to 16S RNA for 4 h, and to 1×10^{-4} to 1 µg of $\delta\beta$ thalassaemia 6 to 16S RNA for 24 h to obtain the C_0t values shown. Hybridisation was performed in a 10-µl reaction mixture at pH 7.0 containing (final concentration): 0.02 M sodium phosphate, 0.1% sodium dodecyl sulphate, 0.3 M NaCl and 0.002 M EDTA at 68 °C. The percentage hybridisation was determined after digestion of single-stranded cDNA with micrococcal nuclease: 4-µl samples of each hybridisation mixture were treated with micrococcal nuclease and 4 µl was used as control for recovery in individual experiments. ▲, α cDNA; △, β cDNA.

No β globin synthesis was demonstrable by column chromatographic analysis when peripheral blood samples containing reticulocytes from β^0 Catania, β^0 Ferrara or $\delta\beta$ thalassaemia samples were incubated with ^{3}H-leucine. A typical chromatographic separation on carboxymethyl cellulose[4] in a patient from Ferrara is shown in Fig. 1. In contrast to previous studies[18], there is no induction of β globin synthesis 22 d after blood transfusion. Similar results were obtained with β^0 Catania cells and with homozygous $\delta\beta$ thalassaemia cells[13]. When mRNAs from $\delta\beta$, β^0 Catania and β^0 Ferrara patients are added to a Krebs' ascites tumour cell-free system (ref. 19 and R. G. and B. L., unpublished) there is also no detectable synthesis of β globin chains. Only α and γ globin synthesis are present.

Using normal reticulocyte 6 to 16S RNA, the relative content of α and β mRNA measured by hybridisation to purified cDNAs is close to 1.0 (Table 1, Fig. 2a). In addition, greater than 90% of the α and β cDNAs are protected from micro-

coccal nuclease digestion by normal reticulocyte mRNA, indicating that all of the nucleotide sequences in the cDNA are represented in the mRNA. Using 6–16S RNA isolated from the δβ thalassaemia homozygote, the α cDNA hybridises to a saturation plateau of 70% at a relatively low C_0t value while at a C_0t value 30–40-fold above this, only 18% of the β cDNA is hybridised (Table 1, Fig. 2b). The background of the hybridisation in the absence of added mRNA is 9%. These data indicate that δβ thalassaemia homozygote mRNA contains no detectable δ or β mRNA sequences, and confirms previous studies[8]. In addition, they show that the β cDNA probe used is contaminated with less than 10% α cDNA. The fact that only 70% of the α cDNA is hybridised in a vast excess of δβ thalassaemia mRNA (Fig. 2b) suggests that the α cDNA is contaminated to approximately 20–25% with β cDNA sequences. Additional evidence supporting this is obtained when the α cDNA is hybridised with hydrops fetalis mRNA (containing no α mRNA)[9]; only 20 to 25% of the α cDNA is protected while β cDNA is hybridised to 85% (Fig. 3a).
Fig. 3 Hybridisation of α and β cDNA with hydrops fetalis (a) and β⁰ Catania RNA (b). 2,000 and 2,500 c.p.m. of α or β cDNA were hybridised to 2×10^{-2} to 10 μg of hydrops fetalis 6 to 16S RNA for 4 h and to 1.3×10^{-4}–6.4×10^{-1} μg of β⁰ Catania 6–16S RNA for 120 h. The hybridisation conditions and analysis are as described in the legend to Fig. 2. ▲, α cDNA; △, β cDNA.

When 6–16S mRNA from β⁰ Catania cells is hybridised to α and β cDNAs, a completely different hybridisation curve is obtained. The $C_0t_{\frac{1}{2}}$ with the β cDNA is 2-and 2.4-fold greater than that with α cDNA indicating 2-to 2.4-fold greater amounts of α than β globin mRNA sequences are present (Fig. 3b, Table 1). Here, 80% of the β cDNA is protected from micrococcal nuclease digestion using the RNA of this patient. Although it is clear from Fig. 3b that almost all of the β cDNA is hybridised and the curve is continuing to descend, a high enough C_0t value was not attained to determine if all of the nucleotide sequences in the β cDNA are present in the β mRNA molecules in the cells of this patient. More extensive studies at higher C_0t values in this and other patients with β⁰ Catania thalassaemia are required to determine if all of the sequences present in intact β mRNA are present. However, the extent of β cDNA hybridisation is clearly different from that of δβ thalassaemia mRNA. These data are consistent with those reported previously in two patients using rabbit globin cDNA probes[6] and in two Chinese patients and a β⁰ patient of Italian extraction[11] suggesting the possibility that there is non-functional β globin mRNA in some patients with β⁰ thalassaemia. Since in these[6,11] and the present studies, less than full-length β cDNA probes are used, even complete hybridisation of the β cDNA would not prove that complete β globin mRNA molecules are present and untranslatable. To do this, studies using full-length cDNA and structural analysis of the β mRNA will be required. The results reported here also do not exclude the possibility that some patients with β⁰ thalassaemia from Catania may have

an absence of β mRNA as has been reported in other β⁰ patients[8,12].

Defect in mRNA from β⁰ Ferrara cells

When β⁰ Ferrara 6–16S RNA is hybridised to the α and β cDNA probes, a different result is obtained from that with normal, δβ or β⁰ Catania mRNA. First, the β cDNA is only hybridised to 46–56% at C_0t values even in mRNA excess 10- to 25-fold greater than that necessary to protect the α cDNA maximally (Table 1, Fig. 4). Using cDNA synthesised from HbH mRNA, similar extents of hybridisation were obtained to those using β cDNA, 45–55%. The $C_0t_{\frac{1}{2}}$ values are an accurate measure of the relative amounts of α and β mRNA present in a sample of RNA[6,9,20]. The $C_0t_{\frac{1}{2}}$ values for α in Fig. 4 are 2×10^{-2} and 9×10^{-2} respectively. If a small amount of intact β mRNA capable of hybridising to all of the β cDNA is present in β⁰ Ferrara mRNA, it must represent less than 5% and 2% of α mRNA since the $C_0t_{\frac{1}{2}}$ of any complete β mRNA must be at least 4×10^{-1} and 6 (highest C_0t values reached) respectively.

Mixing of two β⁰ Ferrara mRNA preparations in different combinations did not increase the percentage hybridisation of β cDNA. By contrast, mixing of β⁰ Ferrara mRNA with hydrops fetalis mRNA or normal mRNA leads to over 90% hybridisation of the β cDNA, indicating that no inhibitor of β mRNA hybridisation is present in the β⁰ Ferrara mRNA samples. When β⁰ Ferrara is hybridised to β cDNA at 78 °C instead of 68 °C, there is a decrease in the amount of cDNA protected from micrococcal nuclease digestion to a background value. The hybridisation of normal reticulocyte mRNA to β cDNA and of normal and β⁰ Ferrara mRNA to α cDNA are unaffected by a similar increase in temperature. The lower level of protection of α cDNA by β⁰ Ferrara mRNA than by normal mRNA can be explained by contamination of α cDNA by β cDNA sequences. This was confirmed by showing that when hydrops fetalis mRNA containing only β and γ mRNA was added to the Ferrara mRNA, 90% of the α cDNA probe could be protected.

In β⁰ Ferrara mRNA, it is clear that different hybridisation results are obtained than with β⁺ and β⁰ Catania and δβ mRNA. Even in large mRNA excess only 46–56% of the β cDNA is hybridised; only about half of the nucleotide sequences present in β cDNA are represented in β Ferrara RNA in significant amounts. This finding cannot be explained by contamination of the β cDNA probe by α cDNA since only 18% of the β cDNA is hybridised at similar inputs of RNA from δβ thalassaemia cells which also contain α mRNA in normal amounts. In all five β⁰ Ferrara patients studied, the defects in β mRNA are similar if not identical since there is no increase in saturation

Fig. 4 Hybridisation of α and β cDNA with β⁰ Ferrara–1 RNA (a) and β⁰ Ferrara–2 RNA (b). Between 2,000 and 2,500 c.p.m. of α or β cDNA were hybridised to 4×10^{-4} μg to 3×10^{-1} μg of β⁰ Ferrara–2 RNA for 8 h, and to 1.2×10^{-4}–8×10^{-2} μg β⁰ Ferrara–1 RNA for 4 h. The hybridisation conditions and analysis were as described in the legend to Fig. 2. ▲, α cDNA; △, β cDNA.
hybridisation with β cDNA when mixing of β⁰ Ferrara mRNA samples were performed.

The possibility that the β cDNA is hybridising with γ mRNA sequences in β⁰ mRNA was studied by comparing the hybridisation of γ cDNA prepared as described previously[21] with δβ thalassaemia and β⁰ Ferrara mRNA. Using both types of mRNA the γ cDNA probe was hybridised at $C_0t_{1/2}$ values two-to threefold less than using α cDNA, indicating approximately one-third to one-half as much γ as α mRNA is present in both of these mRNAs (F.R., J.V.O'D., C. Natta and A.B., unpublished). The hybridisation data support cell-free studies indicating that similar amounts of γ globin mRNA are present in β⁰ Ferrara and δβ mRNA. The results with δβ mRNA indicate that γ mRNA does not cross hybridise with the β cDNA probe in the conditions of hybridisation, and that the difference in the extent of hybridisation of β cDNA to δβ and β⁰ Ferrara mRNA cannot be explained by the presence of γ mRNA.

Several possible mechanisms can explain the 35–45% difference in hybridisation of β⁰ Ferrara mRNA and δβ thalassaemia mRNA with β cDNA. First, β mRNA may be completely absent in these cells, but since δ mRNA is present in β⁰ Ferrara cells, the partial hybridisation may be due to homology between β cDNA and δ mRNA nucleotide sequences. Since β and δ globin chains differ by only 9 of 144 amino acids, significant homology at the nucleotide level is not unlikely. But the relatively low C_0t of hybridisation to β cDNA when compared with hybridisation to α cDNA (Fig. 4) requires a rather large amount of δ mRNA to be present in these cells.

If incomplete or structurally abnormal mRNA existed, the abnormality in β⁰ Ferrara mRNA could be either at the 5' or 3' end of the mRNA outside of the nucleotide sequence necessary to encode β globin; the complete nucleotide sequence in mRNA necessary to encode β globin could be intact, although this mRNA might be more labile than normal mRNA and reports of induction of β globin synthesis by transfusion *in vivo* and addition of supernatant fractions *in vitro* would be possible[18,23]. Regardless of the precise explanation for the limited hybridisation of Ferrara mRNA to β cDNA, the results suggest that the genetic lesion in β⁰ Ferrara is different from that in β⁰ Catania, β⁺ and δβ thalassaemia and is associated with either an absence of β globin mRNA or an abnormal β globin mRNA. The precise nature of the gene defects in the β⁰ Catania and β⁰ Ferrara and perhaps other forms of β⁰ thalassaemia must await analysis of newly synthesised β globin mRNA sequences in the nuclei of erythroid cells in patients with these syndromes.

Deletion of globin gene sequences in δβ thalassaemia

When β cDNA is hybridised to normal DNA approximately 51–56% of the β cDNA is hybridised at similar cDNA : cellular DNA inputs (Table 2). DNA from normal fibroblasts, spleen and white blood cells all give similar levels of hybridisation. When DNA from β⁰ Catania cells is hybridised to β cDNA, approximately 50–55% of the β cDNA becomes hybridised. These results indicate that there is no detectable deletion of

Table 2 Hybridisation of α and β cDNA to cellular DNA

| | Percent hybridisation* | | | |
| | α cDNA | | β cDNA | |
Source of DNA	C_0t : 4,320	C_0t : 8,640	C_0t : 4,320	C_0t : 8,640
Normal – 1	43	39	51	51
Normal – 2	47	49	54	56
Normal – 3	47	46	51	51
HPFH homozygote	35	36	23	22
δβ homozygote	37	41	32	29
δβ heterozygote – 1	44	44	38	41
δβ heterozygote – 2	40	43	41	43
β⁰ Catania – 1	47	46	55	50
β⁰ Catania – 2	45	43	56	54
Hydrops fetalis	21	20	53	53

*In each cDNA–DNA hybridisation, 3.3 × 10⁻⁷ as much cDNA as cellular DNA is used. Forty-five μl aliquots containing 0.135 mg of DNA and 630 c.p.m. (0.045 ng) of either α or β cDNA were mixed in 0.12 M sodium phosphate (pH 6.8) and 0.4% sodium dodecyl sulphate in 100-μl capillary pipettes, heated in a boiling water bath for 15 min and incubated at 68 °C for varying times in order to attain the C_0t values shown. The cDNA eluted from hydroxylapatite at 68 °C by 0.4 M sodium phosphate is expressed as a percentage of cDNA eluted by 0.12 M plus 0.4 M sodium phosphate successively. The values obtained at different C_0t values are shown to indicate a saturation plateau has been reached.

Alternatively, the RNA sequences hybridising to β cDNA may represent Lepore-like globin mRNA in the Ferrara RNA, and the hybridisation to β cDNA due to homology with the β-like sequences in this Lepore-like chain. Or third, there may be a partial deletion of β globin mRNA sequences at the 3' end of Ferrara mRNA. In addition to 50–100 polyadenylate residues at the 3' end of human globin mRNA[22], studies of abnormal elongated human globin mutants suggest that there is an untranslated nucleotide sequence of approximately 100 nucleotides at this end[1]. Since β globin cDNA contains approximately 400 nucleotides and primarily sequences synthesised from the 3' end of mRNA, a deletion at the 3' end of the Ferrara mRNA might result in the findings reported here. Lastly, the presence of normal amounts of a structurally abnormal mRNA with either increased lability or considerable secondary structure must be considered. Such an abnormal RNA might not be fully hybridised to β cDNA. Either cross hybridisation of β cDNA to δ mRNA sequences or an abnormal β mRNA could explain the lability of the β⁰ Ferrara mRNA–β cDNA hybrid.

β or β-like genes in β⁰ thalassaemia. In contrast, when HPFH DNA is mixed with β cDNA only 22–23% of the β cDNA is hybridised at saturation (Table 2). Using DNA from a δβ thalassaemia homozygote, only 32 and 29% of the β cDNA is hybridised, somewhat higher than that using HPFH DNA (Table 2). Similarly, DNA from heterozygotes for δβ thalassaemia show decreased hybridisation to the β cDNA probe to 41 and 43%, respectively (Table 2). To determine if the deletions in HPFH and δβ thalassaemia DNA are overlapping, 0.112 mg of homozygous δβ thalassaemia DNA and 0.113 mg of HPFH DNA were mixed and annealed with 0.045 ng β cDNA to a C_0t of 8,640; 37% of the β cDNA was protected. 0.225 mg of normal DNA gave 59% hybridisation while the same amount of HPFH DNA gave 24% hybridisation with the same input of β cDNA. The data are consistent with overlapping gene deletions in HPFH and δβ thalassaemia DNA with a larger deletion in HPFH DNA.

When α cDNA is hybridised to cellular DNA from normal, HPFH, δβ and β⁰ thalassaemia cells at similar inputs of cDNA

and cellular DNA, relatively similar amounts of hybridisation of the α cDNA are obtained (Table 2). These values indicate that normal, HPFH, and β^0 and $\delta\beta$ thalassaemia DNA all contain similar numbers of α globin genes and serve as a useful internal control of the cellular DNA : cDNA input. There is 5 –10% less hybridisation of α cDNA with HPFH, and 3–7% less hybridisation of α cDNA with $\delta\beta$ thalassaemia DNA from the homozygote than with similar inputs of normal or β^0 thalassaemia DNA (Table 2). This is consistent with β cDNA sequences in the α cDNA probe which cannot be hybridised because of the deletion of β-like cellular DNA sequences. The somewhat higher level of hybridisation of normal DNA to cDNA than to α cDNA (51–56% compared to 39–49%) confirms previous data[9].

Studies to date indicate that in homozygous β^+ thalassaemia[9], β^0 thalassaemia[12] and in a $\delta\beta/\beta^0$ double heterozygote[10] there is no detectable deletion of globin structural genes. In contrast, deletion of globin structural genes has been reported in HPFH homozygotes[15,24]. Our results confirm deletion of β-like globin DNA nucleotide sequences in HPFH DNA (Table 2). Less than half as much hybridisation of β cDNA occurs with HPFH DNA as with similar input of normal DNA. The nature of the sequences in HPFH DNA which hybridise to β cDNA is not yet defined; they may represent incompletely deleted δ and/or β structural gene loci, embryonic β-like genes or cross hybridisation of α gene sequences to the α cDNA contaminating the β cDNA probe.

Deletion of β structural gene sequences has recently been observed by others (S. Ottolenghi *et al.*, unpublished) in patients homozygous for $\delta\beta$ thalassaemia. We have confirmed the deletion of β-like gene material in one of these homozygotes. Further, we demonstrate detectable deletions of β-like gene material in heterozygotes for $\delta\beta$ thalassaemia (Table 2). Our methodology seems to be more sensitive in detecting gene deletions in $\delta\beta$ heterozygotes than hybridisation in vast DNA excess or vast cDNA excess, since such a deletion was not detected by others using these methods[10]. These data are consistent with at least partial deletion of β or δ globin structural genes or parts of both in this disorder. The deletion of structural globin gene sequences in $\delta\beta$ thalassaemia DNA may, in addition, be less than that in HPFH DNA. In both HPFH and homozygous $\delta\beta$ thalassaemia, the only haemoglobin produced is foetal haemoglobin, HbF. In HPFH, sufficient γ globin is produced to maintain normal haemoglobin levels, while in $\delta\beta$ thalassaemia, γ globin production does not compensate and there are cellular abnormalities typical of thalassaemia and consequent haemolytic anaemia. Regulation of γ globin synthesis at the gene level has been postulated to involve regulatory nucleotide sequences adjacent to the δ structural genes[25]. It may be speculated that deletion of these sequences in HPFH permits maximal expression of γ globin genes even in adult life. The differences in hybridisation between HPFH and $\delta\beta$ thalassaemia DNA with β cDNA reported here could reflect the presence of residual sequences in $\delta\beta$ thalassaemia DNA with a suppressive effect on γ globin production. The residual sequences present in $\delta\beta$ thalassaemia and absent in HPFH DNA may generate a gene product which suppresses γ gene activity. Alternatively, no such diffusible gene product acting in *cis* would be required if the sequences we are detecting in $\delta\beta$ thalassaemia which are absent in HPFH are adjacent to the γ globin genes and are involved in the normal suppression of γ globin gene activity in adult life. These speculations do not exclude the possibility that other genetic interactions may control γ gene expression.

Recently, a patient with β^0 thalassaemia has been described in whom there is absence of β mRNA but no apparent deletion of β-like genes[12]. In the present and previous studies[9,12] of patients with β^0 and β^+ thalassaemia who have intact δ globin loci, it is possible that cross hybridisation between β cDNA and δ gene sequences can obscure the detection of small deletions in β structural genes. In addition, the use of less than complete length β cDNAs in all of the studies reported to date

of gene deletion in β and $\delta\beta$ thalassaemia make it possible that deletions of β-like sequences in DNA at the end of β or δ genes homologous to the 5' end of β globin mRNA may exist and remain undetected in these syndromes.

The common denominator of the β thalassaemia syndromes is decreased β globin synthesis with inadequate γ globin compensation. The decrease in β globin production in β^+ thalassaemia is associated with decreased β globin mRNA and is due to either a defect in regulatory genes controlling β structural gene expression or the production of a structurally abnormal β gene product which is partially destroyed during RNA processing in the nucleus. In one patient with β^0 thalassaemia, absent β mRNA is associated with no detectable deletion of β globin genes[12]. On the other hand, as demonstrated in this paper, the absent δ and β mRNA in $\delta\beta$ thalassaemia is associated with deletion of δ and/or β gene material. In some β^0 thalassaemia patients[6,11] including one from Catania described here there are significant amounts of incomplete or complete β mRNA sequences in cells which are untranslated and may reflect a small abnormal nucleotide sequence in the β globin gene. This report provides evidence that β^0 Ferrara may differ from other forms of β^0 thalassaemia described to date and is associated with either abnormal or absent β mRNA. Thus, the β thalassaemia syndromes represent a heterogeneous group of disorders at the genetic level, all of which lead to decreased β globin production.

Enzyme evolution in a microbial community growing on the herbicide Dalapon

E. Senior & A. T. Bull*

Biological Laboratory, University of Kent at Canterbury, Canterbury CT2 7NJ, UK

J. H. Slater

Department of Environmental Sciences, University of Warwick, Coventry CV4 7AL, UK

A seven-membered microbial community capable of utilising the herbicide Dalapon has been isolated by continuous-flow enrichment culture. The composition of this community has remained remarkably stable over thousands of hours in a Dalapon-limited chemostat. During this period, however, one member of the community, Pseudomonas putida, acquired the ability to grow on Dalapon through the evolution of an extant dehalogenase.

IN most natural environments different populations of microorganisms grow in close proximity to each other and may utilise similar substrates present in the ecosystem. One likely consequence of this is that various nutritional and physical interactions will develop between the populations leading to the evolution of complex, mutually dependent and possibly highly stable microbial communities. It is reasonable to postulate that interacting microbial communities are common in nature; however, very few microbial associations of this type have been defined, principally because inappropriate enrichment and selection techniques have been used to isolate them from natural environments.

The aims of the work reported here was to use suitable continuous-flow culture enrichment procedures[1,2] to isolate a microbial community which could grow on the herbicide 2,2'-dichloropropionic acid (Dalapon, Dow Chemical Company) as its sole source of carbon and energy. Dalapon is a widely used herbicide which is effective against monocotyledons and is known to undergo microbial degradation[3]. Such a compound was selected because it was argued that mixed populations possessing diverse metabolic capabilities are more likely to be able to metabolise recalcitrant or semi-recalcitrant compounds than are populations composed of a single species. In addition, it seems to be the general case that so called 'environmentally foreign' compounds are degraded much more rapidly in natural environments than they are by monocultures of microorganisms grown in similar conditions in the laboratory. Such observations provide circumstantial evidence for cooperative metabolic attack by a microbial community.

Characterisation of isolated microbial community

Figure 1 describes the structure of the microbial community which has been isolated on several occasions from four different soil sources, two of which had been pretreated with Dalapon. Initially, after three weeks growth in the chemostat enrichment system, the mixed culture consisted of seven different microorganisms which could be divided into two groups. The first group comprised the primary utilisers which, in monoculture, were able to grow on Dalapon as the only carbon and energy source. In all four microbial communities originally isolated, three primary utilisers were

found; two were Gram-negative, motile rod bacteria, one of which (P1) was identified as a *Pseudomonas* species of Shewan's group II (ref. 4) the other (P2) remains unidentified. The third Dalapon utiliser was a filamentous fungus, *Trichoderma viride* (P4). The other group contained the secondary utilisers which were unable to grow on Dalapon in monoculture in any growth conditions. These secondary organisms must have been growing on metabolites which were produced directly from the primary catabolism of Dalapon, or metabolites excreted by the growing primary utilisers, or on compounds freed into the growth medium as a consequence of the death and lysis of primary and secondary utilisers. The non-Dalapon utilisers were three bacteria —a *Flavobacterium* species (S1), *Pseudomonas putida* (S3), and an unidentified pseudomonad (S4)—and a pink budding yeast (S5). The quantitative species composition remained very stable with changing growth conditions with the exception of the two major primary Dalapon utilisers; at low dilution rates in the chemostat (less than $0.25\ h^{-1}$) the bacterium P2 was the dominant primary organism whereas at high dilution rates (greater than $0.45\ h^{-1}$) *Pseudomonas* species P1 dominated.

Stability of the community

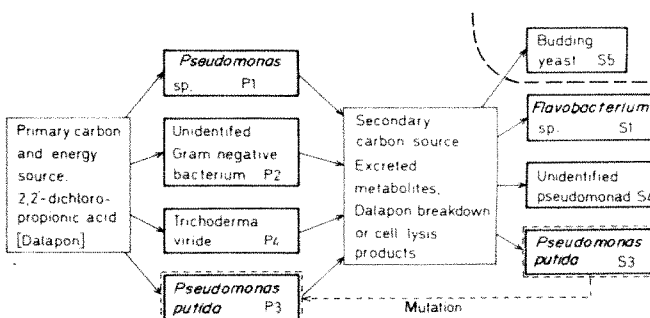
The yeast was only loosely associated with the microbial community and was eliminated from the enrichment chemostat the first time the dilution rate was raised above $0.2\ h^{-1}$.


Fig. 1 The structure of the microbial community growing on 2,2'-dichloropropionic acid. The chemostat enrichment cultures had a volume of 0.5 l and were operated at a dilution rate (*D*) of $0.015\ h^{-1}$. The growth medium consisted of (g l^{-1}): K$_2$HPO$_4$, 1.5; KH$_2$PO$_4$, 0.5; (NH$_4$)$_2$SO$_4$, 0.5; MgSO$_4$.7H$_2$O, 0.2; Dalapon, mixed Na and Mg salts (Dow Chemical Company, UK) 1.65; pH 7.3. Several enrichments were set up using as inocula, *a*, culture effluent from a soil column containing a sandy loam (*p*H 4.8) which had been pretreated with Dalapon (the column had been perfused with Dalapon-containing minimal medium for several weeks before some of the culture effluent was used as the inoculum) and *b*, soil, either sandy loam or sandy chalk, which had or had not been pretreated with Dalapon, added directly to the chemostat. The enrichment cultures were monitored for biomass (culture absorbance and dry weight), species composition, pH and residual Dalapon concentration (determined by measuring chloride ions in solution by modification of Mohr's method[6]).

*Present address: Department of Applied Biology, University of Wales Institute of Science and Technology, King Edward VII Avenue, Cardiff CF1 3NU, UK.

The remaining six-membered association was exceedingly stable, however. One of the isolated communities was cultured for over 7,500 h at constant growth rate and environmental conditions with no qualitative change in the species composition. A second six-membered community has been continuously grown in a Dalapon-limited chemostat for over 13,500 h, which corresponds to approximately 3,700 generations. Throughout this period, and in spite of repeated environmental perturbations and changes in the specific growth rate, only one significant change in the community's character has been detected and this is described later. This particular community has been subjected to regular changes in dilution rate, such that seven continuous cycles of increasing and decreasing growth rate have been completed.

In the first cycle (Fig. 2) the dilution rate was increased by small increments and steady-state cultures were established at each value. At growth rates below $D=0.25$ h^{-1} the culture pH remained approximately constant at 3.3. The reduced pH in the poorly buffered growth medium and in the absence of fermenter pH control was due to the complete breakdown of the available Dalapon and the concomitant production of HCl. With a further slight increase in the dilution rate there was a marked rise in the culture pH to 6.1. This shift in pH was simultaneously accompanied by an increase in the unused Dalapon concentration and a decrease in the culture biomass. Further increases in the dilution rate, up to a maximum of 1.1 h^{-1}, caused further increases in the pH up to a maximum of 6.9. When the dilution rate was gradually decreased to complete the first cycle of dilution rate changes, a reverse hysteresis-like pattern of pH change was observed with the rapid phase of pH decline occurring at dilution rates between $D=0.19$ and 0.17 h^{-1}.

With successive cycles of changing dilution rate, the rate of pH change decreased until, by the seventh cycle, the pH change took place gradually over almost all the dilution rate range examined; moreover, in these later cycles the culture pH did not fall to the original low values. These observations indicated that to some extent the microbial community gradually stabilised, without qualitative changes in the species composition of the association, to dampen and minimise the environmental changes which occurred with changes in the dilution rate. The overall effect was to reduce the potentially deleterious influence of rapid pH fluxes.

During the increasing phase of the first dilution rate cycle (Fig. 2), the sudden pH shift was accompanied by an immediate development of heavy growth on the walls throughout the chemostat vessel. When the dilution rate was decreased the wall growth disappeared once the pH values had dropped to ~ 4.0. In later cycles the appearance of wall growth was much more gradual, probably because the change in pH was correspondingly less rapid. In all these latter cycles, however, heavy wall growth became reestablished when the pH had risen to greater than 5.0. The composition of the wall growth was complex, but it contained all the individual species of the microbial community originally present in free suspension. The attached surface growth was dominated by the mycelia of *Trichoderma viride*, however, and this contrasted markedly with the microflora in suspension at the same dilution rates, from which the fungus was virtually absent. At the lower dilution rates, and hence at low pH values, hyphae of *T. viride* were dispersed homogeneously in the culture. The development of wall growth prevented washout of the culture at dilution rates exceeding the maximum specific growth rate of the community and effectively preserved the integrity of the community in such circumstances. Submerged liquid batch and agar plate cultures of *T. viride* growing on Dalapon proved that the fungus readily metabolised the herbicide and grew vigorously at low pH values whereas at pH>6.0
Fig. 2 The change in steady-state culture pH for the six-membered microbial community growing in a Dalapon-limited chemostat during the first cycle of increasing and decreasing the dilution rate. ○, Steady-state pH values in the increasing dilution rate phase; ●, pH values during the decreasing dilution rate phase. Heavy wall growth dominated by *T. viride* was established at growth rates in excess of $D = 0.28$ h^{-1}, during the increasing dilution rate phase, and had disappeared between $D = 0.19$ and 0.17 h^{-1} during the decreasing stage.

growth was extremely sparse. Thus fungal growth on the internal surface of the chemostat seemed to be a response to unfavourable conditions, namely high pH values, which developed at high dilution rates, and an attempt to create a favourable microenvironment within the chemostat where low pH conditions could be established and maintained.

New primary Dalapon utiliser

The significant change in the nature of the microbial community, first noticed after 2,900 h of continuous growth, was the appearance of a fourth primary Dalapon utiliser, subsequently identified as *P. putida* (P3) and identical in all other respects to the secondary utiliser, *P. putida* S3. It seemed possible that P3 had arisen as a mutation of S3 during the prolonged period of growth under Dalapon-limited conditions. The evolvant was retained within the community, together with its parent S3, and did not seem to unbalance the system. It is interesting that the selection of another primary utiliser should have occurred in spite of the presence of the three original primary utilisers and the inevitable increase in competition for the growth-limiting nutrient. Indeed the presence of three or four primary utilisers apparently contradicts the kinetic theory of enrichment cultures[5,6] which predicts that the organism with the greatest affinity for the limiting nutrient (that is, the lowest saturation constant) or the highest maximum specific growth rate will be the most successful in competing with others. In open systems, such as continuous-flow cultures, the most competitive organism ought to cause the elimination of the less competitive population. Our observations strongly indicate that several, so far unidentified, interactions occur between the individual populations of the whole community and these serve to stabilise free competition between the primary utilisers. The catabolism of Dalapon by hydrolysis to pyruvic acid and free chloride occurs as a result of the activity of the enzyme dehalogenase[3]. Thus *P. putida* P3 could have arisen either by the acquisition of Dalapon-metabolising capability by plasmid transfer from one of the original primary utilisers, or, by the selection of a mutant having a modified dehalogenase activity enabling it to metabolise Dalapon.

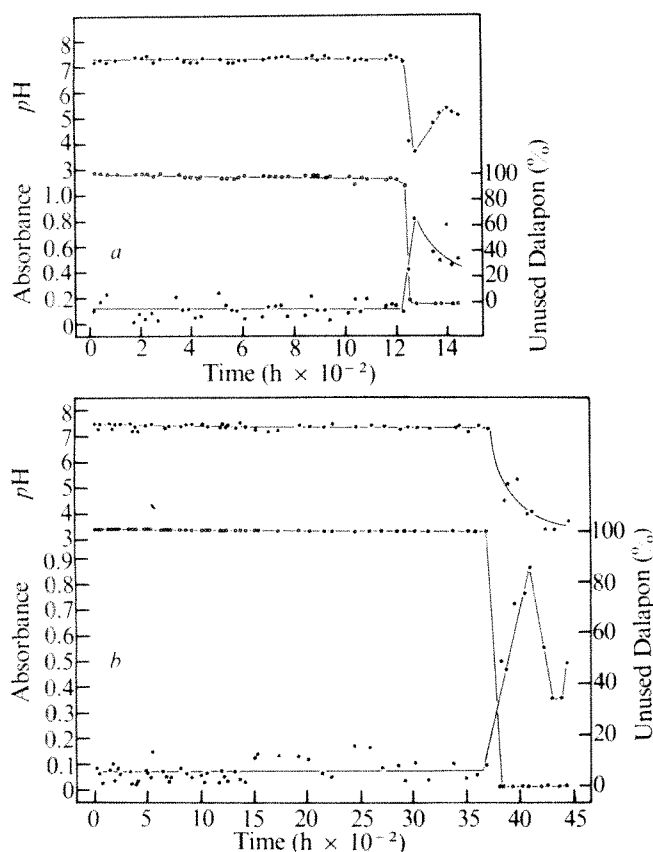
The latter hypothesis has been verified in monoculture chemostat studies. *P. putida* S3, isolated from the microbial community and purified could not grow on Dalapon in


Fig. 3 *a* and *b*, Two experiments demonstrating the evolution of Dalapon-metabolising *P. putida* P3 from the non-Dalapon-metabolising *P. putida* S3. See text for details. Lower ●, culture absorbance (E_{625}); ○, unused Dalapon as a percentage of the concentration in the inflowing medium. Top ●, culture *p*H.

a range of environmental conditions. A culture of *P. putida* S3, grown on sodium propionate, was inoculated into a chemostat containing a minimal growth medium with the carbon source as the growth-limiting substrate and operating at a dilution rate of 0.05 h⁻¹. The carbon source was a mixture of sodium propionate (0.07 g carbon l⁻¹) and Dalapon (0.35 g carbon l⁻¹) which gave a carbon ratio of 1 : 5. S3 was initially able to grow only on the propionate carbon and thus could be retained in the open culture system and at the same time be continuously exposed to a non-utilisable carbon source. Accordingly evolvants with the capacity to utilise the additional carbon source might be expected to have a considerable selective advantage if they could acquire the capacity to metabolise Dalapon.

Figure 3*a* and *b* shows the results of two such evolution experiments. In the first experiment (Fig. 3*a*) a steady-state culture of strain S3, growing solely on propionate was established with a culture absorbance of approximately 0.1, a situation that was maintained for just over 1,200 h of continuous growth in constant environmental conditions. During the first stage of the experiment the culture *p*H remained constant at its initial value of 7.4, suggesting that no Dalapon was being metabolised. This conclusion was confirmed by measuring free chloride in the culture and calculating the percentage of Dalapon which had been metabolised. After 250 h of growth a small number of Dalapon-metabolising colonies were detected on dilution plates. Initially the detection of such colonies was variable but with time their frequency of detection increased until they were found in every sample taken from the chemostat. The presence of Dalapon-metabolising individuals within the population did not immediately result in their competitive selection and displacement of the S3 population.

After 1,200 h of growth, however, such an event did occur and was manifest as an approximately fivefold increase in the culture absorbance, a result which would be anticipated if the evolvant population were able to utilise the additional carbon source. Metabolism of Dalapon was indicated by a concomitant decrease in culture *p*H and an increase in free chloride in the culture. Within 30 h the evolvant **P3** succeeded in establishing a new steady-state culture and completely displacing the original S3 strain. In the new steady state the Dalapon concentration in the chemostat was reduced to zero. A similar sequence of events has been observed in five other experiments, the only variation being the time at which the Dalapon-metabolising population managed to replace the parent strain. In a second experiment (Fig. 3*b*) for example, the mutational event leading to the selection of the P3 strain occurred much later, after 3,750 h of continuous growth, in conditions identical to those of the first experiment.

Preliminary dehalogenase analyses have shown that during the first 3,750 h of growth of *P. putida* S3 (Fig. 3*b*) there was no dehalogenase activity with a specificity towards Dalapon. After the mutational event and the establishment of the new steady-state culture however, Dalapon-specific dehalogenase activity was detected (E. Senior, C. Larvin, J. H. Slater and A. T. Bull, unpublished). In addition, we have obtained evidence which shows that the dehalogenase originally possessed by *P. putida* S3 had a specificity towards 2-monochloropropionic acid and that the evolvant P3 has a markedly increased specific activity of the 2-monochloropropionic acid-specific dehalogenase (J. H. Slater, D. E. Sanders and A. T. Bull, unpublished). Growth experiments have indicated that *P. putida* S3 will grow slowly on 2-monochloropropionic acid as its sole carbon source, whereas P3 grows vigorously on this substrate.

Enzyme evolution

Experimental enzyme evolution is an area that has excited growing interest over the past decade and elegant demonstrations of the evolution of enzymes with new specificities and activities have been provided by studies of the aliphatic amidases of *P. aeruginosa*[7] and the pentitol dehydrogenases of *Klebsiella aerogenes*[8]. The chemostat offers considerable scope for investigating the evolutionary potentialities of microorganisms, principally because it enables the imposition of precise selection pressures on a population. The putative evolution of *P. putida* dehalogenase is a further vindication of this experimental approach and it is worth emphasising that it was achieved without the intervention of specific mutagens. Moreover, we would like to emphasise the value of mixed microbial populations in enzyme evolution studies in two important respects. First, within such a mixed system multiple selective pressures can operate which are analogous to those occurring in real ecosystems. Second, in the microbial community we have begun to analyse it is clear that the biochemical and physical nature of the whole system provides a permissive environment for metabolic evolution. In particular, the secondary species, by virtue of the fact that they are continuously supplied with assimilable substrates by the activity of the primary utilisers, are retained within the community and thus are continuously exposed to a non-metabolisable compound. Indeed it is clear that for enzyme evolution experiments in monoculture a metabolisable 'carrying' substrate has to be provided to ensure that the single species population continues to grow and be exposed to the non-metabolisable substrate for long periods. We are now attempting to elucidate the precise nature of the dehalogenase in the parent *P. putida* and its relationship to the evolvant strains and to explore the extent to which the catalytic activity of this enzyme can be modified to deal with different chlorinated aliphatic

acids. E.S. thanks the SRC for a research studentship. We thank the Dow Chemical Company for supplying Dalapon; A. Gallenkamp and Co. Ltd, for assistance with fermentation systems and Professor H. Veldkamp and Dr W. Harder for discussions.

Partial purification of rabbit aorta contracting substance-releasing factor and inhibition of its activity by anti-inflammatory steroids

F. P. Nijkamp, R. J. Flower*, S. Moncada & J. R. Vane

Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS, UK

Rabbit aorta contracting substance-releasing factor (RCS-RF) is found in perfusates from guinea pig lungs during anaphylaxis. It has been identified as a small peptide which releases arachidonic acid from lung tissue, thus generating prostaglandin endoperoxides and thromboxanes and causing bronchoconstriction. Anti-inflammatory steroids block the release of arachidonate by RCS-RF. In this activity their relative potency is very similar to their relative anti-inflammatory potency, suggesting that the two actions may be related.

PIPER and Vane[1] detected the release of additional substances into the perfusate during anaphylaxis in isolated lungs from sensitised guinea pigs. Because of its activity they called one "rabbit aorta contracting substance" or "RCS". RCS was unstable at room temperature and its release was blocked by aspirin-like drugs. RCS has now been identified as a mixture of the prostaglandin cyclo-endoperoxides (PGG_2 and PGH_2) and thromboxane A_2 (TXA_2)[2,3]. The RCS activity is mainly due to TXA_2. Piper and Vane also found that after the RCS activity of the perfusate declined, another much more stable substance could be detected. This was called "RCS-releasing factor" or RCS-RF because effluent containing RCS-RF injected into the pulmonary artery of perfused lungs from unsensitised guinea pigs induced a release of "RCS". We have now isolated and partially purified RCS-RF, which seems to be a small peptide. RCS-RF stimulates the generation of PG endoperoxides and TXA_2 probably by releasing the precursor arachidonic acid from lung tissue. Steroid anti-inflammatory drugs block this releasing action and thus prevent the generation of TXA_2, whereas non-steroid anti-inflammatory drugs block the generation of TXA_2 by a direct effect on the prostaglandin cyclo-oxygenase enzyme. The rank order of nine steroid drugs as inhibitors of RCS-RF activity correlates well with their rank order as anti-inflammatory substances.

Isolation, partial purification and assay

The assay procedure for RCS-RF and SRS-A like activity is described in the legend to Fig. 1. Lungs were removed from male guinea pigs (200–300 g) which had been sensitised

---

*To whom all correspondence should be addressed.

to ovalbumin (100 mg subcutaneously and 100 mg intra-peritoneally) 2–4 weeks earlier. The lungs were perfused through the pulmonary artery with Krebs' solution at 10 ml min^{-1} as previously described[1]. Anaphylactic shock was induced by injection into the pulmonary artery of 10 mg ovalbumin and the perfusate was collected for 10 min (about 100 ml). Effluent from 5–10 sensitised lungs was pooled, centrifuged (5,000g for 30 min) to remove cells, filtered and stirred for 30 min with 30 g l^{-1} Amberlite XAD-2 (BDH) to adsorb the RCS-RF activity. After filtering under vacuum to remove the Krebs' solution the Amberlite XAD-2 was washed with small volumes of distilled water,

Fig. 1 For bioassay of RCS-RF the effluent from unsensitised lungs was allowed to superfuse a rabbit aortic strip, a rat fundic strip, a rat colon and guinea pig trachea in cascade[1]. Sensitivity and selectivity of the tissues were increased by an infusion into the lung effluent of "combined antagonists"[1] to prevent the actions of histamine, acetylcholine, catecholamines and 5-hydroxy-tryptamine as well as indomethacin (1 μg ml^{-1}) to prevent endogenous synthesis of prostaglandins by the tissues[4]. SRS-A-like activity of samples was estimated using the isolated guinea pig ileum[5] preparation, hyoscine hydrobromide (10^{-7} g ml^{-1}) and, where appropriate, mepyramine maleate (10^{-7} g ml^{-1}) was added to the organ bath to prevent spontaneous activity and render the preparation insensitive to histamine[5]. PP, Pulmonary artery perfusion pressure; RA, rabbit aortic strip; RSS, rat (fundic) stomach strip; RC, rat colon; GPT, guinea pig trachea; OT, injection directly over the tissues; TL, injection into the pulmonary artery; AA, arachidonic acid.

Table 1 Partial purification of RCS-RF

Extraction procedure	Weight of sample	RCS-RF-like activity (Total units)	Yield (%)	Specific activity (U mg^{-1})	Purification factor
None. Original effluent lyophilised*	6.64 g	3,534.23	100	0.53	0
Amberlite XAD-2 extraction	245.6 mg	1,473.77	41.70	6.06	11.43
Diethyl ether extraction	236.9 mg	1,208.71	34.20	5.10	9.62
Paper chromatography	0.22 mg	692.12	19.58	3,146.00	5,935.84

The extraction efficiencies vary from experiment to experiment and the figures quoted in this table should only be regarded as a guide.
*Starting material was 570 ml effluent.

and the RCS-RF recovered from the resin with 40-50% yields (see Table 1) by washing with 1.5 l ethanol–water (80 : 20, v/v). The ethanol–water extract was evaporated *in vacuo* in a rotary film evaporator, and the dried residue was washed three times with dry diethyl ether to remove lipids (thin-layer chromatography of the ether washings revealed substantial quantities of fatty acids, prostaglandins and some phosphatides). After ether washing the residue was dissolved in a small aliquot of distilled water: this preparation, referred to as the "crude fraction", possesses potent RCS-RF activity and is stable for at least 6 weeks when kept frozen.

For further purification, the crude fraction was streaked on to a silica gel-impregnated paper chromatogram (Whatman SG81) which was developed by ascending chromatography in ammonia–*n*-propanol–water (30 : 60 : 10, v/v). After developing to a distance of 20 cm, the chromatogram was removed, dried and cut into 1-cm horizontal sections. There were eluted with small volumes of distilled water and the biological activity assayed.

About 80% of the RCS-RF activity was associated with a single band of R_f 0.7 (see Fig. 2). A small amount of RCS-RF activity was also recovered from a zone running ahead of the major peak and sometimes small amounts were detected close to the origin (see Fig. 2). In addition to the RCS-RF activity, there were several zones containing activity which contracted the guinea pig ileum, indicating SRS-A like activity. One of these corresponded to the bulk of the RCS-RF activity, and others to the minor RCS-RF zones. We regarded the major zone of releasing activity as "RCS-RF" and referred to this fraction as the "partially purified" fraction. The biological activity of the partially purified fraction is shown in Fig. 1. Partially purified RCS-RF has no "direct" effect over the smooth muscle organs but when injected into isolated perfused lungs from guinea pigs it provoked an immediate increase in perfusion pressure, a bronchoconstriction (not shown), and a release of RCS; prostaglandins E_2 or $F_{2\alpha}$ were seldom detected.

The partially purified fraction was stable for several weeks when kept frozen. The releasing activity of RCS-RF was potentiated three- to fivefold by concomitant injections of 10 μg of an inhibitor of carboxydipeptidase activity BPP-5A (ref. 6). We defined "1 unit" (U) of RCS-RF as that amount which when injected into the lung released the same amount of RCS-activity (TXA$_2$) as 1 μg of arachidonic acid.

Physicochemical properties

RCS-RF is insoluble in ether, chloroform, ethyl acetate, acetone and ethanol but is more soluble in methanol (about 70% of its water solubility). It is destroyed by drastic *p*H changes, being more susceptible to acid rather than alkaline *p*H values. For example, a 1-h incubation with 1 N HCl completely inactivated RCS-RF but a 1-h incubation with 10 N NaOH still left about 20% of the activity. RCS-RF loses 75% activity after boiling for 10 min, but was unaffected by boiling for 1 min. Passage through a dialysis

membrane suggests a small molecule of <5,000 molecular weight.

The activity of RCS-RF is not reduced by incubation with phospholipase A, C or D (Sigma) (100 μg enzyme per ml) but was reduced slightly (~15%) by incubation with trypsin (Sigma) (500 μg enzyme per ml). In two out of four experiments, incubation with arylsulphatase (Sigma) (500 μg ml^{-1}) produced 50–60% inactivation; SRS-A is also inactivated by this enzyme. Incubation with carboxypeptidase B (Sigma) (500 μg enzyme per ml for 1 h at 37 °C) or aminopeptidase M (Sigma) (100 μg enzyme per ml for 1 h at 37 °C) resulted in an 80–85%, or complete inactivation (respectively), strongly suggesting that RCS-RF is a peptide. When a freshly developed paper chromatogram was sprayed with ninhydrin reagent, which reacts with α-amino acyl groups of amino acids, the zone containing RCS-RF was only one of several ninhydrin-positive areas. RCS-RF was not found in the perfusate of non-sensitised lungs challenged with antigen and, unlike RCS, was not released by mechanical trauma. The limited physicochemical data obtained so far are compatible with RCS-RF being a peptide of less than 10 amino acids.

Effects of inhibitors

The release from sensitised lungs of RCS-RF by antigen was not prevented by aspirin (200 μg ml^{-1}), in the perfusing fluid, indomethacin (2 μg ml^{-1}), dexamethasone (2 μg ml^{-1}), disodium cromoglycate (20 μg ml^{-1}), colchicine (5 μg ml^{-1}), diethyl carbamazine (1 mg ml^{-1}), or mepacrine (20 μg ml^{-1}). Aspirin, indomethacin, mepacrine and dexamethasone (same concentrations) all blocked the release of TXA$_2$ from the

Fig. 2 Biologically active material recovered from the paper chromatogram. Top panel RCS-RF-like activity assayed as shown in Fig. 1; bottom panel SRS-A-like activity, assayed as described in Fig. 1.
		Table 2	ID_{50} Values for some anti-inflammatory steroids	
Steroid	ID_{50} (nmol min^{-1})	Inhibition (%) of arachidonic acid at ID_{50}	Relative (molar) potency	Relative anti-inflammatory potency*
Dexamethasone	34.4	− 0.3	35.1	25.0
Betamethasone	36.5	− 7.3	33.1	25.0
Triamcinolone	106.1	+31.1	11.4	∼5.0
Fludrocortisone	133.0	−21.9	9.1	10.0

Prednisone	185.8	− 2.3	6.5	4.0
Corticosterone	968.9	−32.84	1.3	0.35
Cortisone	1,206.8	+ 9.12	1.0	0.8
Hydrocortisone (cortisol)	1,207.0	− 11.9	1.0	1.0

The following drugs were used: dexamethasone sodium phosphate (Decadron, Merck Sharp and Dohme) or dexamethasone (Sigma); betamethasone (Betsolan, Glaxo); triamcinolone acetonide (Kenalog, Squibb); fludrocortisone (Sigma); prednisolone acetate (Deltastab, Boots); prednisone (Koch-Light); corticosterone (Sigma); cortisone (Sigma); and hydrocortisone sodium succinate (Efcortelan, Glaxo). All steroids were infused for 15 min, and the amounts indicated are calculated as the base. Apart from the soluble esters, steroids were dissolved in ethanol and diluted 9:1 (v/v) with 0.9% saline. Each result is the mean of three or four observations.
*Data taken from ref. 8.

lung provoked by RCS-RF. All these substances except dexamethasone also prevented the conversion of exogenous arachidonic acid into TXA₂, confirming that they act by a direct block of cyclo-oxygenase[4]. Dexamethasone, however, blocked the release of TXA₂ by RCS-RF without affecting the conversion of exogenous arachidonic acid to TXA₂, implying a different site of action. We therefore examined the effects of other steroids in this system. Table 2 shows that all the steroids tested blocked the releasing activity of RCS-RF. Furthermore, their relative activity in this test closely paralleled their reported anti-inflammatory activity. The steroids had variable but generally only small

Mechanism of action and site of steroid blockade

Infusion of arachidonic acid into perfused guinea pig lungs leads to an immediate synthesis of TXA₂ suggesting that substrate availability is a rate-limiting step in this system. RCS-RF may, therefore, act by liberating arachidonate from some intracellular pool, and steroids could be preventing this effect. To test this possibility, we perfused isolated lungs with Krebs' solution containing 5,8,11,14-eicosatetraynoic acid (TYA)—an acetylenic analogue of arachidonate—at 10 μg ml^{-1}. This prevented metabolism of any

Table 3 Release of arachidonate from lungs by RCS-RF

Lung effluent was collected for 5–7 min following an injection of RCS-RF either in the presence or absence of blocking doses of steroids. The pH of the effluent was adjusted to 3.0 with 1 N HCl and the arachidonate extracted with ether, a small amount of 1-¹⁴C-arachidonate was added as a tracer. After concentration of the sample *in vacuo* the fatty acids were methylated with diazomethane and separated on thin-layer chromatography silica gel plates impregnated with 10% AgNO₃ (Uniplates, Anachem) by development in n-hexane, diethyl ether, acetic acid (50:50:1 v/v). The methyl arachidonate zone was located with a radiochromatogram scanner and eluted with ether, and the arachidonate content was estimated with a Pye Unicam series 104 gas chromatograph, using a 5-foot column packed with 10% DEGS on Gas-Chrom Q. With an oven temperature of 195 °C methyl arachidonate was easily detected by the flame ionisation detector, having a retention time of about 8 min. The labelled arachidonic acid was used to correct for losses during sample manipulation. Large doses (5–10 U) of RCS-RF were used to ensure that easily detectable amounts could be liberated, and correspondingly higher doses of steroids were used to compensate for this.

effects on the conversion of arachidonic acid to TXA₂, which were unrelated to their anti-RCS-RF activity. The release of TXA₂ by arachidonate, for example, was unaffected by dexamethasone, potentiated by triamcinolone and depressed by fludrocortisine. These effects could be related to the vehicle in which the steroid was dissolved; for ethanol (used to dissolve some of the steroids) in concentrations greater than 10 μl ml^{-1} depressed the release of TXA₂ by arachidonate.

There were two other notable features concerning the block of TXA₂ release by anti-inflammatory steroids; first, a maximal effect was obtained only after infusing each steroid for 10–20 min. Second, the inhibition produced by steroids was easily overcome by increasing the amount of RCS-RF. Thus, the ID_{50} of a steroid will depend on the concentration of the agonist.

released arachidonate by the lung, TYA being an inhibitor of both the cyclo-oxygenase and lipoxygenase pathways of arachidonate metabolism[9,10]. Table 3 shows that both "partially" purified and "crude" RCS-RF liberated arachidonate from lungs and that this release was blocked when any of the steroids was present. Thirty minutes after stopping the steroid infusion, arachidonate release by RCS-RF returned, indicating that the effects of the steroids in this system were relatively short lived and easily reversed.

The actual amounts of arachidonate released from lungs varied greatly between experiments (see Table 3, experiments 4–7) but were relatively consistent in single lungs (experiments 1–3). Although the samples were collected for 5–7 min it should be realised that the evoked release of arachidonate usually takes place within 1 min giving an effect similar to a bolus injection of the substrate. It is

interesting to note that there is a continuous basal release of arachidonate from the isolated lungs. This was generally found to increase with time (experiments 1–3, Table 3). In one experiment (No. 4) at least, betamethasone actually lowered the stimulated release below basal levels. This observation correlates with an effect frequently observed during steroid infusion—a decline in tone of the bioassay organs, suggesting a decreased basal TXA_2 output.

What is the source of the arachidonic acid liberated by RCS-RF? Although amounts of free arachidonic acid in many tissues are small (see ref. 11) considerable quantities are present in ester form in the neutral lipid or phosphatide fractions. Several observations (see ref. 11) indicate that phospholipids are the chief source of arachidonate in cells, so that the phospholipase enzyme system may be stimulated in some way by RCS-RF. Some evidence for this possibility has already been obtained in this laboratory (G. J. Blackwell, R.J.F. and F.P.N., unpublished). Specifically labelled (2'-(1-^{14}C)-oleoyl) lecithin is partially (~ 1–3%) hydrolysed when perfused through the isolated lung—presumably by a phospholipase A_2. The rate of hydrolysis is doubled when concomitant injections of 5 U RCS-RF were given, and decreased when infusions of dexamethasone or betamethasone (178.8 nmol min^{-1}) were made. Phospholipase A_2 activity in guinea pig lung homogenates, however, was not affected by the anti-inflammatory steroids, suggesting that these drugs only have a blocking action in intact cells.

RCS-RF and anaphylaxis

We do not know whether RCS-RF formation and release contributes to anaphylaxis in guinea pigs. It does not seem to have any intrinsic smooth muscle activity in the doses we used here. Our finding that it cannot be recovered from the lungs of unsensitised animals or from unchallenged sensitised lungs would suggest that it is not stored in the lung, but is elaborated in response to the immunological stimulus. Thus, if it does have a role in anaphylaxis it could be among those substances classified as "primary mediators" by Austen and Orange[12]. If it is a peptide, RCS-RF cannot be the SRS-A of Orange *et al.*[7], a conclusion reached earlier by Piper and Vane[1] on the basis of biological evidence. Although there seem to be similarities between SRS-A and RCS-RF, any formal relationship between the two compounds (as suggested by the arylsulphatase inactivation experiment) awaits further clarification.

Of great interest is the finding that anti-inflammatory steroids block the RCS-RF induced release of thromboxane. Even though they do not inhibit the cyclo-oxygenase[13] there has been increasing evidence that one steroid (hydrocortisone) interferes in some way with prostaglandin biosynthesis in several other systems[14–17]. The mechanism proposed by Lewis and Piper[14] to account for hydrocortisone action, that of an inhibition of a cellular transport mechanism, does not operate here since arachidonate consistently reversed the steroid block. Instead, our results point to a mechanism of action much earlier in the biosynthetic pathway—the inhibition of substrate liberation from intracellular stores. A similar hypothesis has already been advanced by Gryglewski and his colleagues[15]. This store is probably the phosphatide fraction of the cell, and the enzyme responsible for liberation of the acid, the cell membrane phospholipase A_2. Bradykinin is another peptide which releases RCS from the lung[18] and, like RCS-RF, its activity is potentiated by BPP-5A. We find, however, that only RCS-RF activity is steroid sensitive, implying that it activates a very selective enzymatic step.

The order of potency of the steroids in inhibiting RCS-RF activity is striking similar to the order of anti-inflammatory potency, and the possibility that inhibition of substrate release is a general method by which anti-inflammatory steroids can interfere with the synthesis of prostaglandin (or other arachidonate metabolites) must be considered.

letters to nature

Cosmic rays near the galactic centre

THE galactic centre (GC) is characterised by objects of high activity: there are powerful sources of infrared radiation, radio waves and X rays, and evidence for a small region (~ 1 pc) of extremely high luminosity (~ $10^8 L_\odot$). The presence of a ring of gas (very largely molecular hydrogen)[1] at a distance of ~ 300 pc from the GC also indicates violent activity. It is reasonable to assume that there is also an increased cosmic-ray intensity at least for energies ≲ 10 GeV. The presence of protons and electrons having such energies together with high gas densities and high starlight intensities provides the ingredients for significant γ-ray fluxes. Here we examine the implications of recent measurements of the γ-ray flux from the region of the GC, with particular reference to the 300-pc ring.

The most comprehensive γ-ray data so far obtained are those from the SAS-II satellite (see ref. 2). The earlier data did not give strong evidence for a peak at l^{11} ~ 0° but a very recent reanalysis by Fichtel *et al.*[3] shows a rather impressive peak (see Fig. 1) which offers the possibility of deriving the cosmic-ray intensity in the GC region. It should be remarked, however, that the only other precise cosmic γ-ray experiment, that on the COS B satellite[4], does not show a peak near l^{11} = 0°. The analysis so far is described as "preliminary", however, and we are of the view that the peak is still very probably genuine.

Although the SAS-II peak looks rather broad (FWHM ≃ 6°) most of this is instrumental and it seems that the bulk of the radiation is coming from within about ±2° of the GC. The distribution thus seems to be both narrower and of higher
Fig. 1 The flux of γ rays above 100 MeV for longitudes close to the GC, from Fichtel *et al.*[3]. ● ● ●, Estimate of the contribution for $R > 350$ pc, where we assume that the cosmic-ray intensity is proportional to the mean surface gas density. *a*, Contribution from electrons by way of the inverse Compton effect, assuming a constant electron flux throughout the Galaxy[4].

intensity than estimated for inverse Compton interactions by Dodds *et al.*[5] (see Fig. 1) for the case of an electron intensity near the GC similar to that locally (and with a full width for the electron distribution of 500 pc). There is thus evidence for an increase in the cosmic-ray intensity near the GC.

The original SAS-II data have been analysed by many authors and it has been shown that there is almost certainly a gradient of 1–10-GeV cosmic-ray protons in the Galaxy. Our view is that the firmest evidence comes from the analysis of measurements towards the galactic anti-centre[6] but the most reasonable interpretation of γ rays from the inner Galaxy is that there is a gradient there too, with the cosmic-ray intensity roughly following the average surface gas density[7] and the surface density of supernova remnants and pulsars[8,9] (at least for $R \gtrsim 4$ kpc). Such a correlation would be expected if the cosmic-ray lifetime is roughly constant for $R \gtrsim 4$ kpc, in which case the intensity will be proportional to the generation rate.

Near the GC we might expect the generation rate to be again roughly proportional to the gas density, and in what follows we examine whether this is the case.

The SAS-II data of Fig. 1 indicate a flux of γ rays from within a few degrees of the GC of $\sim 6.7 \times 10^{-4}$ cm^{-2} s^{-1}. This value has been derived using as a datum for non-centre flux the distribution shown dotted in Fig. 1; in the calculation the contribution from the rest of the Galaxy followed from the assumption that the cosmic-ray intensity is proportional to mean surface gas density.

Locally, the escape times for electrons and protons are roughly equal and therefore the e–p ratio is expected to be the same as at generation. In the GC region the lifetime against energy loss is about the same for electrons and protons (see later) and so we expect their intensities to be enhanced by the same factor (F) over their local values. The procedure is to calculate F so that the measured flux of γ rays at the Earth is reproduced.

The first contribution arises from the decay of π^0s produced by protons and heavier cosmic-ray nuclei interacting with the

interstellar matter at the GC. For the mass of gas and its distribution we use the measurements of Scoville and Solomon[10] which indicate that there is about $5 \times 10^7 M_\odot$ of molecular hydrogen distributed within a radius of ~ 350 pc and a volume of $\approx 10^7$ pc^3. Assuming that the cosmic-ray spectrum has the same spectral shape as that locally, the expected flux of γ rays above 100 MeV at the Earth is $\sim 6.8 \times 10^{-7}$ F cm^{-2} s^{-1}. Although there will be a contribution from inverse Compton interactions of electrons in the starlight field, in the present model this will be outweighed by the yield from bremsstrahlung interactions. We assume that the lifetime for escape of the cosmic-ray nuclei from the ring is significantly greater than 10^5 yr, the lifetime against interaction. The protons will then be in equilibrium with the secondary electrons from $\pi \to \mu \to e$ The electrons, too, are assumed to be absorbed before escaping from the ring, bremsstrahlung predominating (the mean lifetime is $\sim 2 \times 10^5$ yr at 1 GeV). Ramaty[11] has given the generation spectrum for electron secondaries and from this the secondary electron intensity has been derived. As an example, the derived intensity at 1 GeV is $\sim 12\%$ of that of primary protons in the ring. To this must be added $\sim 3\%$ for primary electrons giving a total electron intensity at 1 GeV in the ring of 15% of the proton intensity.

At electron energies of ~ 100 MeV ionisation losses predominate over bremsstrahlung and the γ rays at 100 MeV are mainly from π^0 decay. This implies $F \simeq 10$.

A value for F (to be denoted F_a) can also be calculated from non-thermal radio observations of the GC if we assume that there is a coupling between the cosmic-ray energy density and that in the magnetic field. Measurements at 408 MHz (ref. 12) suggest a brightness temperature of 100 K from the 300-pc molecular ring ($\sim 4 \times 10^{-4}$ sr) region, of which we estimate $\sim 25\%$ to be thermal[13]. Using a lifetime against bremsstrahlung of 2×10^5 yr, the equilibrium electron intensity has been calculated. Equating the calculated synchrotron flux to observations gives $F_a \simeq 12$. This is rather larger than the value of F calculated from the γ-ray flux but it is not inconsistent considering uncertainties in the electron lifetime and the likely underestimate of the percentage of thermal radiation.

The value $F = 10$ derived from the γ-ray analysis can be used to derive the relative generation rates in the ring, where the lifetime is $\sim 10^5$ yr, and locally, where we assume that the lifetime by escape is $\sim 2.5 \times 10^6$ yr. The ratio ring-to-local value is ~ 250; this can be compared with the ratio of gas densities, $\sim 200{:}1$. The nearness of the results adds some weight to our original contention.

We thank Drs T. M. Bania, J. L. Osborne, N. V. Scoville and A. W. Strong, Professors W. Butler Burton and P. M. Solomon, and Mr D. Dodds for discussions. Dr C. E. Fichtel and his colleagues kindly made available their new γ-ray data. D. M. W. thanks the SRC for a studentship.

The 35-d X-ray profile of Her X-1

FOLLOWING the report from Ariel V (ref. 1) of substantial X-ray emission from Her X-1 midway through the extended low-state portion of its 35-d cycle, Jones and Forman[2] have reported a similar feature during another cycle, measured from Uhuru. They further suggest that this feature should occur regularly, consistent with models for the mass accretion disk which are inclined with respect to the binary orbital plane[3,4]. We report here the results of the analysis of > 500 d of Ariel V all-sky monitor (ASM) data, which support the view that the feature occurs regularly in the 35-d cycle.

The Ariel V ASM is barely sensitive to Her X-1 under the most favourable of viewing constraints (see ref. 5 for a complete description of the apparatus). Its sensitivity for accumulation times $\gtrsim$ 0.5 d is no better than $\sim$ 0.1 the intensity of the Crab Nebula (approximately the maximum intensity of Her X-1), so that considerations, such as occultation by the Earth, make the average sensitivity of the experiment even poorer. During the total duration of observation reported here (October 16, 1974 through April 16, 1976), a total of 803 data accumulations of $\leqslant$ 0.5 d, for which Her X-1 was not either outside or at the very edge of the experiment field-of-view, have been obtained. Only 24 of these allow intensity definition at the 2σ level (corresponding to $\sim$ 3σ detection of a positive signal above background). Of these 24 measurements, all but one were within the 'on-time' of the 35-d cycle, and a full 1/3 were obtained from a single cycle during which the viewing constraints were near-optimum. It is important to note that the same maximum source intensity produces, for average viewing conditions, a < 1σ signal.

We can, however, take advantage of the fact that we can differentiate between null statistical results under optimum viewing conditions (corresponding to a knowledge that the source was not at maximum intensity), and those at more unfavourable conditions (for which no such knowledge can be gleaned). All the data were, therefore, normalised to the same viewing constraints, with individual negative measurements of the intensity relative to background initially defined to be zero. These 803 points, excluding measurements centred within 7 per cent of the 1.7-d Her X-1 eclipse minimum, were then folded at various trial periods near 35 d. In Fig. 1, where we have plotted the total variance for a 15-bin light curve compared to the average value (essentially equivalent to a χ^2 test against the hypothesis of a constant source intensity), the 35-d modulation of the normalised record is apparent. Figure 1 alone prescribes a period of 34.7±0.3 d (where the width of the variance peak is consistent with the overall sample duration), in agreement with the 34.88±0.12 d of ref. 6. A comparison of the shape and phase of the on-state portion of the light
Fig. 2 34.9-d light curve of Her X-1 in 15 bins. The ordinate is normalised to approximate Uhuru counts for comparison with other measurements. The epoch of the start of bin 1 is JD 2,442,442.0.
curves obtained here with those of ref. 6 clearly favours a value of 34.9±0.1 d.

The 34.9-d light curve is exhibited in Fig. 2, where the negative intensity measurements are now properly included in the folding procedure (allowing both consistent error estimates and a zero baseline intensity to be obtained). In addition to the characteristic reproduction of the on-state portion of the cycle (bins 1–5), bin 11 contains a > 3σ excess relative to the surrounding off-state intensity. This feature does not arise primarily from the single off-state measurement of high statistical significance, as that datum contributes to bin 12. Jones and Forman have reported that the analagous feature they observed in Uhuru data near January 1, 1972 represented $\sim$ 30% of the maximum intensity, with a duration of $\sim$ 15% of the 35-d cycle (between φ = 0.45 and φ = 0.6 relative to φ = 0 at maximum). The present data agree with the magnitude of the effect, but differ somewhat in phase and duration. In the Ariel V data, the feature is centred at φ = 0.55±0.05 relative to maximum, with an apparent duration of $\leqslant$ 10% (at an intensity $\gtrsim$ 1/4 of maximum). The agreement in magnitude of the present feature with that obtained from Uhuru, coupled with the fact that it is never statistically detectable in an individual measurement, strongly implies that it occurs regularly in every cycle at $\sim$ 1/3 of maximum.

Jones and Forman have attempted to refine model disk geometry parameters on the basis of the Uhuru data, but the present measurements are obviously too crude to revise sensibly their estimates. Clearly, a high-sensitivity measurement of this portion of the light curve is required, and our results would suggest that this experiment is possible during any Her X-1 cycle.

Fig. 1 Variance for 15-bin light curves as a function of trial period. The ordinate is normalised to the mean for trial periods 32.0–33.0 d and 36.0–38.0 d.

Microwave spectral lines from interstellar dust

SPECTRAL features at 3.07, 10, 20 and 33 μm have proved invaluable in the chemical characterisation of interstellar dust[1,2]. As spectral observations are extended into the far infrared, it is likely that other features attributable to the absorption and emission of radiation by dust will be observed. To date there has been no discussion in the literature on the possibility of discrete spectral features attributable to dust at even longer wavelengths. The purpose of this note is to suggest that relatively sharp spectral lines may arise from neutral or ionised atomic species in interstellar dust at mm and cm wavelengths. The detection of these spectral features would provide definitive information on the chemical composition of interstellar dust.

The 21-cm line of atomic H arises from the $F = 0 \longleftrightarrow F = 1$ hyperfine transition of ground state H atoms. H atoms can be found in many different types of solid or on solid surfaces (Table 1) when these solids are subjected to nuclear irradiation. The $F = 0 \to F = 1$ transition for H atoms in these systems occurs at the frequencies shown in Table 1. The list has been chosen as representative of solids of astrophysical interest, but it is by no means complete. It serves only to show that H atoms can be stabilised in many types of solid astrophysical interest. H atoms in these environments will absorb or emit radiation at frequencies within $\pm \sim 30$ MHz of 1,420 MHz. The width of the hyperfine line as measured in ESR experiments is typically 0.3–3 MHz. This width arises primarily through spin-lattice coupling[3] for temperatures $\lesssim 50$ K and would be smaller in an astrophysical environment where coupling to lattice acoustic phonons will be diminished, because of the small size of interstellar grains. This effect, which has been seen[4] in laboratory ESR spectra of powders, arises because spin-lattice relaxation at low temperatures involves the creation

Table 1 Frequency of H atom $F = 0 \to F = 1$ hyperfine transition in various solids

of acoustic phonons whose energies are close to that of the hyperfine transition. In small particles a cutoff of the acoustic phonon spectrum occurs at $v_c \simeq v_s/2a$ where v_s is the speed of sound in the solid[5] ($\simeq 10^5$ cm s^{-1}) and a is the particle radius. The value of $v_c \simeq 5 \times 10^9$ Hz, for $a = 10^{-5}$ cm; and $\simeq 5 \times 10^{11}$ Hz for $a = 10^{-7}$ cm. Both these frequencies are $> 1,420$ MHz, and thus single-phonon spin-lattice relaxation would not be important for H atoms in interstellar grains. Broadening due to spin–spin interactions, which is proportional to spin concentration[3], could be important in larger particles but would not be expected to be significant in small particles containing only a few H atoms. We conclude that $\Delta v \simeq 0.3$–3 MHz is likely to be an upper limit to the width of the 21-cm line for H atoms trapped in interstellar grains.

H atoms could be formed in interstellar grains through the action of cosmic rays or photons from the interstellar ultraviolet radiation field. Alternatively, H atoms from the ambient gas may collide with and stick to grains. To estimate the column density required to yield measurable absorption one can use the relationship between n_HL, the number of H atoms in grains per cm^2, and the optical depth τ_v given by Kerr[6].

$$n_HL = 3.88 \times 10^{14} T_s \tau_v \Delta v$$

where T_s is the excitation temperature, and Δv is the linewidth in Hz. Taking $T_s = 10$ K as typical of the temperature of an interstellar grain, $\tau_v = 10^{-2}$ and $\Delta v = 10^5$ Hz, one has $n_HL = 3.9 \times 10^{18}$ cm^{-2}. Then, n_gL, the column density of grains $= 3.9 \times 10^{18}/n$ where n is the number of H atoms per grain. For a 1% concentration of H atoms in grains one obtains $n_HL \simeq 10^{24}$ cm^{-2} independent of the choice of a when the usual mass ratio of gas to dust is used and the dust is assumed to consist of a material with density $\simeq 2$ g cm^{-3} made up of the heavier elements. Though column densities as great as this are not found in typical interstellar clouds, they may be found in protostar clouds or regions of strong infrared absorption or emission[1].

Zero-field splitting[3] of the ground state of many transition metal ions in solids occurs when the crystal field partially removes the M_J degeneracy of states with $J > 1/2$. As an example, the ground state of Fe^{3+} is $^6S_{5/2}$ in the free ion. In a crystal with other than cubic symmetry, this state splits into 3 doubly degenerate levels with $m_J = \pm 1/2, \pm 3/2$ and $\pm 5/2$. Magnetic dipole transitions with $\Delta m_J = 0, \pm 1$ are permitted between these levels. Table 2 shows that these transitions occur in the frequency range between 6 and 80 GHz. In a crystal field with cubic symmetry (MgO, CaO) the ground state of Fe^{3+} splits into only 2 levels, and in that case a single spectral line is ob-

served. Taking a spectral line at $v = 100$ GHz with $\Delta v = 10$ MHz as typical of these transitions one obtains

$$n_{Fe}L \simeq 2 \times 10^9 \, T_s \tau_v \Delta v$$

where

$$T_s = 10 \text{ K}, \, \tau_v = 10^{-2}, \text{ and } n_gL \simeq 2 \times 10^{15}/n$$

where n is the number of Fe^{3+} ions per grain. The corresponding hydrogen column density is $N_HL = 10^{21} \text{ cm}^{-2}$ when one assumes a Fe^{3+} concentration in dust of 1%. Our conclusion is that transitions between the zero-field levels of Fe^{3+} or other transition metal ions in interstellar dust may be observable in absorption in typical interstellar dust clouds.

Though we have emphasised the possibility of detecting absorption features attributable to dust in the mm and cm regions it may be more practical to search for emission features. Grains should be relatively transparent in this region, because of the absence of optical phonon modes at such low frequencies. This implies that most of the energy radiated by grains at mm and cm wavelengths will be radiated within these spectral lines. In view of the optical pumping of interstellar grains that occurs through absorption of short-wavelength photons from the interstellar radiation field, non-thermal emission at the frequencies of these discrete features is a distinct possibility. Microwave lines at 81.541 GHz and 43.122 GHz, attributed to emission from rotational levels of the SiO $v = 1$ state[22], are both within 0.2 GHz of the zero-field lines from Fe^{3+}–TiO_2 (Table 2).

Force-free magnetic fields in the fluid interiors of neutron stars

I SHOW here that, in equilibrium, the magnetic field in the fluid interior of a neutron star satisfies the condition $\mathbf{B} \times \nabla \times \mathbf{B} = 0$, which is the usual condition for a field to be force free[1]. The significance of this result is that it places a great theoretical restriction in the possible structure of such fields. Restrictions such as this are important because it is still very difficult to deduce anything from observation about the magnetic fields inside neutron stars.

In the region of the star considered here, the density lies between approximately $2 \times 10^{14} \text{ g cm}^{-3}$ and a few times this

value. The material in that region is a fluid composed of neutrons, protons and electrons[2,3]. It is a simple matter to extend the proof to include the effects of muons and hyperons which may appear at higher densities[2]. Although calculations indicate that the neutrons are superfluid and the protons are superconducting at the temperatures expected inside neutron stars[2,3], the proof of the force-free nature of the field does not depend on these assumptions. Newtonian gravitational theory is used here; the general relativistic proof is essentially similar. The proof may also be extended to rotating neutron stars by including centrifugal terms in the chemical potentials.

The crucial part of the argument is that the dynamical β-equilibrium between the neutrons, protons and electrons requires that

$$\mu_e + \mu_p = \mu_n \qquad (1)$$

where the μs are chemical potentials. These potentials include rest mass energies, Fermi energies and gravitational potential energies per particle. The potentials also depend to a very slight degree on the magnetic field strength[1]. The equilibrium of the neutrons implies that their chemical potential is constant throughout the region

$$0 = -\nabla \mu_n \qquad (2)$$

This equation expresses the hydrostatic equilibrium of the neutrons.

But $-\nabla \mu_e$ and $-\nabla \mu_p$ do not vanish in the presence of a magnetic field, unlike $-\nabla \mu_n$, because both the electrons and protons experience Lorentz forces. If the electron and proton analogues to equation (2) are added together, the result is an equation expressing the magnetohydrostatic equilibrium of the electron–proton plasma

$$0 = -\nabla(\mu_e + \mu_p) + \frac{1}{cn_p} \mathbf{J} \times \mathbf{B} \qquad (3)$$

In deriving the equation, which holds in the centre-of-mass frame of the plasma, charge neutrality ($n_e = n_p$) has been used. It follows directly from equations (1), (2) and (3) that

$$\mathbf{J} \times \mathbf{B} = 0 \qquad (4)$$

where the conduction current density is denoted $\mathbf{J}$. No distinction is made here between the magnetic field $\mathbf{H}$ and the magnetic induction $\mathbf{B}$ because the magnetic permeability is effectively unity. At the densities considered here, the spacing between Landau levels is very much smaller than the Fermi energies (V. Canuto, unpublished). In addition, for a wide range of reasonable temperatures and field strengths, the spacing is smaller than, or comparable to, kT. As a result of these conditions the de Haas–van Alphen oscillations in the magnetic permeability can be neglected.

Because of the previously noted slight dependence of the chemical potentials on the magnetic field strength, there is a small force on the plasma attributable to the magnetic field. But for the reasons mentioned with regard to the magnetic permeability, this force is relatively insignificant (ref. 4, and I.E., unpublished).

It follows from equation (4) that $\mathbf{B}$ satisfies

$$\mathbf{B} \times \nabla \times \mathbf{B} = 0 \qquad (5)$$

which is known as the 'force-free' condition[1].

It should be noted that this condition on $\mathbf{B}$ is true in spite of a small force on the plasma, resulting from the field. The reason the magnetic fields in many other astrophysical plasmas are believed to be force free or nearly so is the smallness of the plasma pressure compared to the magnetic pressure[1]; the

reason for the force-free nature of the field in the neutron star fluid interior is entirely different. The essential point here is that in β-equilibrium, the electrons and protons 'communicate' with each other through the neutrons, causing $-\nabla(\mu_e + \mu_p)$ to vanish, in turn causing $\mathbf{J} \times \mathbf{B}$ to vanish. Furthermore, since the standard stability analyses of force-free fields do not take rotation into account[1], they are not applicable to many neutron stars, in which rotation may profoundly affect the interior plasma dynamics (refs 5 and 6, and I.E., unpublished).

As one simple example of the theoretical use to which equation (5) can be put, note that it can eliminate from consideration any non-singular, purely toroidal field, such as that used by Vandakurov[7].

A rare event in the stratosphere

PERTINENT to the question of the existence of haze and water vapour in the stratosphere[1,2] was the detection of a nacreous cloud at 25 km over New Mexico on June 20, 1974. This occurred just before the volcanic dust incursion from Fuego in November, 1974 (ref. 3), during a high altitude balloon experiment in which a large polar nephelometer was used to measure the optical angular-scattering characteristics of atmospheric aerosols[4].

The balloon launch was made at 0748 MST from Holloman AFB, New Mexico (32°N, 107°W) into a very clear sky. The nephelometer reached an altitude of 26.6 km and payload ground-impact was 7 h later near Silver City, New Mexico, 210 km W of the launch site. Easterly winds of ~ 20 knots carried the experimental package on a trajectory perpendicular to the San Andres mountain range. The minimum ambient of −75 °C was reached at 16.8 km, and the balloon was still ascending when the very strong signal was encountered on the lee side of the mountains. The intense signals continued to the apogee of the flight at 26.6 km without diminution, thereby implying a greater vertical extent for the increased aerosol particle concentrations. The balloon was allowed to float at this maximum altitude for 15 min, evidently immersed in the cloud. Moreover, the signals continued for a period of 50 min, during which time the balloon had travelled nearly 50 km with respect to the ground, thus making the latter distance the minimum horizontal extent of the cloud. On the descent of the balloon, the scattering ceased as dramatically as it had developed on ascent.

Figure 1 shows a typical altitude profile of the volume scattering function (the absolute intensity) measured at a scattering angle of 15° and spectral wavelength of 0.475 μm. Four other photometers, at angles of 30°, 50°, 100° and 150° gave a similar intensity enhancement, although proportionately reduced by the characteristic forward trend of scattering from large particles. The high intensity at ground level (1.29 km above sea level) is caused by exhaust smoke from the balloon launch crane, while that from 3–7 km results from increased amounts of aerosol particles in the convective mixing layer. The stratospheric haze is graphically illustrated by the large variations in intensity as a result of altitudinal inhomogeneity in the particle concentration. The payload also apparently descended through a Cirrus cloud at ~ 10.6 km.

The unusual occurrence of a large haze cloud at 25 km—though it was not evident from the ground—was fortuitous, and is rarely observed in summer at mid-latitudes. Stanford and Davis[5] have made a review of stratospheric cloud reports for the period 1870–1972, and of some 183 sightings only 3 were reported in the USA. Of these three, two events occurred near the San Andres mountains and the remaining one in northern Arizona. This suggests that the mountains of New Mexico may cause the development of stratospheric clouds; however, their visual observation is
Fig. 1 The 15° volume scattering function against altitude at a wavelength of 0.475 μm.

difficult because of their high altitude and tenuous structure. Nonetheless, the rarity of sightings may result in part simply from a lack of observation facilities (or an observer) rather than infrequency of occurrence of such events.

Finally, this cloud provides experimental evidence relevant to Scorer's[2] suggestion, that, even in the absence of volcanic dust, air–mass interchange mechanisms across the tropopause can result in extensive haze formations at high altitudes. Moreover, observations made *in situ* logically provide more reliable information on the stratospheric optical environment, since atmospheric dynamics in the troposphere not only produce sundry effects in the stratosphere but complicate, in particular, remote measurements, since scattering properties along the ground-to-stratosphere light transmission path must be considered.

Gas phase chemical kinetics of sodium in the upper atmosphere

THE existence of a layer of atomic sodium in the upper atmosphere near 90 km has been clearly demonstrated by analyses of daytime and twilight airglow emissions of D-line radiation at 5,890 and 5,896 Å (refs 1 and 2) as well as by direct laser backscatter measurements (see, for example ref. 3). Following Chapman[4] chemical reactions involving atomic sodium and atmospheric oxygen species have been invoked to explain the chemical dynamics of the sodium layer and the nightglow emission of D-line radiation. In addition, Chapman has also proposed that similar reactions involving newly ablated sodium are responsible for the occurrence of long enduring visible meteor trails[5]. Unfortunately, previous quantitative attempts to model sodium-induced upper atmospheric chemiluminescence have suffered from rather poor estimates of the appropriate reaction rate constants. Here we provide more reasonable estimates of rate constants and show how these new kinetics parameters can dramatically alter calculations of chemiluminescent efficiency.

The sodium–oxygen atmospheric reaction sequence is:

$$Na + O_3 \xrightarrow{k_1} NaO + O_2 \qquad (1)$$

$$NaO + O \xrightarrow{fk_2 \text{ and } (1-f)k_2} \begin{cases} Na\,(^2P) + O_2 & (2a) \\ Na\,(^2S) + O_2 & (2b) \end{cases}$$

$$NaO + O_3 \xrightarrow{k_{3a} \text{ and } k_{3b}} \begin{cases} NaO_2 + O_2 & (3a) \\ Na + 2O_2 & (3b) \end{cases}$$

$$Na + O_2 + M \xrightarrow{k_4} NaO_2 + M \qquad (4)$$

$$Na + O + M \xrightarrow{k_5} NaO + M \qquad (5)$$

$$NaO_2 + O \xrightarrow{k_6} NaO + O_2 \qquad (6)$$

$$Na(^2P) \xrightarrow{k_7} Na\,(^2S) + h\nu\,(D_1, D_2) \qquad (7)$$
where all species are in their electronic ground states unless otherwise noted. The combination of reactions 1, 2a and 7 in

Table 1 Ionisation data for sodium and oxygen species

Species	IP (eV)	EA (eV)	Reference
Na	5.14		19
NaO	6.5		12
O_3		1.99	20
O		1.46	21

the presence of O and O_3 in the upper atmosphere form a chemiluminescent chain and may explain both sodium nightglow and meteor trail emissions. Reaction 7 is sufficiently fast ($k_7 = 1/\tau_{rad} = 6.3 \times 10^{-9}$ s^{-1}) that all Na (^2P) created in reaction 2a radiates before quenching at upper atmospheric densities. Recent observations of the nightglow D-line profiles are consistent with this sodium oxide chemiluminescent cycle[7,8].

Several recent attempts to model sodium–oxygen chemistry in the upper atmospheric sodium layer[1,2,9] and in meteor trail wakes[10] quantitatively have been published. These efforts have been severely hampered by the fact that experimental rate constants are only available for reactions 5 and 7. To overcome this handicap, most authors have adopted experimental

Table 2 Calculated reactive cross sections, rate constants and exothermicities for sodium–oxygen reactions

Reaction	σ_R(cm^2)	k_R(cm^3 s^{-1})	ΔH_R^0 (kcalorie mol^{-1})
1	6.5×10^{-15}	3.3×10^{-10}	-34.8 ± 4
2	2.6×10^{-15}	1.6×10^{-10}	$a - 9.2 \pm 4$ $b - 57.7 \pm 4$
3	3.2×10^{-15}	1.4×10^{-10}	$a - 97.2 \pm 7$ $b - 150.2 \pm 7$

rate constants for reactions of either atomic H or N and OH or NO in place of atomic Na and NaO. Values of the order of 10^{-11}–10^{-13} cm^3 s^{-1} for k_1 and 10^{-11} cm^3 s^{-1} for $k_{(2a+2b)}$ are typical in these studies.

Unfortunately, these rate constant estimates are very likely to be substantially low. Exothermic bimolecular processes, like reaction (1) between low ionisation potential species such as alkali atoms and electrophilic molecules such as O_3 are known to occur by an electron jump mechanism[11]. Since the measured ionisation potential of NaO is only 6.5 ± 0.7 eV (ref. 12), it is quite likely that reactions (2) and (3) proceed by electron jump mechanisms as well.

Relatively accurate reactive cross sections for exothermic electron jump reactions can be calculated by determining the radius at which the Coulombic attraction of the ion pair formed by the electron jump, equals the energy deficit between the ionisation potential of the metal containing reactant, IP, and the electron affinity of the electrophilic reactant, EA

$$e^2/r_x = \text{IP} - \text{EA} \qquad (8)$$

The calculated reactive cross section is merely[11,13]

$$\sigma_R \simeq \pi r_x^2 \qquad (9)$$

Using the thermochemical parameters shown in Table 1, equations (8) and (9) can be used to estimate overall reactive cross sections for reactions (1), (2) and (3). Rate constants for these reactions can also be estimated by multiplying the reactive cross sections by the most probable relative velocities for reactant pairs at typical upper atmospheric temperatures.

Table 2 shows reactive cross sections and rate constants for an ambient temperature of 185 K calculated by the procedures outlined above. Table 2 also lists the exothermicities of reactions (1), (2) and (3) calculated using the Na–O bond strength of 60.3 ± 4 kcalorie mol^{-1} measured by Hildenbrand and Murad[12], the Na–O_2 bond strength of 65 ± 3 kcalorie mol^{-1} measured by McEwan and Phillips[14] as well as O–O and O–O_2 bond strengths

of 118.0 and 25.5 kcalorie mol^{-1}, respectively. Furthermore, the Na–O, Na–O$_2$ and O–O bond energies can be combined to yield an estimate of the NaO–O bond strength of 122.7 ± 7 kcalorie mol^{-1}.

It should be noted that the rate constants for reactions (1) and (2), listed in Table 2 are significantly larger than the analogous rate constants for hydrogen or nitrogen species used in previous modelling efforts[1,2,9,10]. As an example of the impact these larger rate constants can have on an atmospheric modelling problem, the upper limit of Na D-line emissions from a ~ 30-g meteoroid with a velocity of 40 km s^{-1} will be calculated below. Following Baggaley[10] such a meteoroid is assumed to deposit a line density of atomic Na of 2×10^{15} cm^{-1}. Atmospheric abundances and common molecular diffusion coefficients, D, are also adopted from Baggaley's work and are shown in Table 3. The values adopted for O and O$_3$ number densities are reasonably consistent with recently published measurements[15-17].

The reaction scheme used in the calculation of meteor trail D-line luminosity consists of reactions (1), (2), (3a), (4), (5) and (7) listed above. Calculations were performed with the branching fraction, f, in reaction 2 set equal to 1 to yield an upper limit to the D-line emission. Reaction (6) is deleted since the bond values listed above indicate that it is close to thermoneutral and is probably slow at mesospheric temperatures. The exclusion of reaction 6 makes NaO$_2$ a chain-terminating species in night-time conditions. Only the 'a' channel of reaction (3) was considered. Inclusion of (3b) would have hindered NaO$_2$ formation and yielded a higher photon production term.

The rate constants for reactions (1), (2) and (3) were used as calculated and listed in Table 2. The rate for reaction (4) has been measured by Carabetta and Kaskan[18] in flame studies and was found to equal 8.2×10^{-34} cm^6 s^{-1} between 1,420 and 1,600 K, independent of temperature. This rate was adopted for both three-body processes (4) and (5). Reaction (7) is essentially instantaneous on the time scale of mesospheric collisions.

The set of equations describing the interaction of meteor deposited Na with the atmospheric oxygen species may be written

$$\frac{d}{dt}[Na] = D\nabla^2[Na] - k_1[Na][O_3] + k_2[NaO][O]$$
$$- k_4[Na][O_2][M] - k_5[Na][O][M]$$

$$\frac{d}{dt}[NaO] = D\nabla^2[NaO] + k_1[Na][O_3] - k_2[NaO][O]$$
$$- k_3^a[NaO][O_3] + k_5[Na][O][M]$$

$$\frac{d}{dt}[NaO_2] = D\nabla^2[NaO_2] + k_3[NaO][O_3]$$
$$+ k_4[Na][O_2][M]$$

$$\frac{d}{dt}[O_3] = D\nabla^2[O_3] - k_1[Na][O_3] - k_3[NaO][O_3]$$

$$\frac{d}{dt}[O] = D\nabla^2[O] - k_2[NaO][O] - k_5[Na][O][M]$$

$$I = f\Sigma k_2[NaO][O] \text{ photons s}^{-1}\text{ cm}^{-1}$$

where ∇^2 is the Laplacian operator in cylindrical coordinates. Reaction with meteor-produced atomic oxygen is not included in this model since Baggaley's treatment indicated that this
Fig. 1 Maximum D-line photon emission rates at 85 and 90 km.

effect does not persist past the first 10 s[10]. An initial meteor train radius of 100 cm was assumed.

Solution of the set of equations listed above was performed using a modified Crank–Nicholson finite difference approach. Solutions of I_m, the maximum photoemissions ($f = 1$), for both the 85- and 90-km cases are shown in Fig. 1. The maximum photon emissions found in this study are 4.6×10^{14} and 7.5×10^{14} photons s^{-1} cm^{-1} at 90 and 85 km, respectively. These compare with peak values of 8×10^{10} and 3×10^{11} calculated by Baggaley using a k_1 of 10^{-13} and a k_2 of 10^{-11} cm^3 s^{-1}. The slow decay of photon intensity after 100 s seen in the 85-km solution is caused by chain-terminating formation of NaO$_2$ due to the deletion of reaction 6.

The large increases (> 10^3) in calculated maximum D-line photon emissions due to the use of more realistic sodium–oxygen reaction rates are clearly important in determining if Chapman's proposed mechanism[5] can be responsible for long lived visible meteor trails at high altitudes. Although no definitive statement can be made without a firm knowledge of f, the branching fraction for excited sodium production in reaction (2), the results shown in Fig. 1 clearly lend more support to Chapman's proposal than Baggaley's recently published calculation[10].

Some feeling for the magnitude of f can be obtained by comparing observed nightglow emissions with those predicted by reactions 1–7 using our rate constant estimates. Quantitative precision is difficult because of the wide variations observed in both ambient Na densities and D-line nightglow densities[2,3,7]; however, a value of f between 10^{-1} and 10^{-2} would seem necessary to match observed nightglow intensities.

It should be noted that the rate constants calculated in this work indicate that sodium is an extremely efficient catalytic destroyer of odd oxygen, (O + O$_3$), at the atmospheric altitudes considered. This efficiency may extend to lower altitudes depending on the magnitude of k_6, the photodissociation cross section for NaO$_2$, and the rate of heterogeneous removal of sodium oxides.

Late Weichselian geomagnetic 'reversal' as a possible example of the reinforcement syndrome

A LATE Weichselian geomagnetic reversal has been reported[1,2] from Sweden. Mörner and Lanser[3] believed the Swedish reversed palaeomagnetic record to be a "real dipole magnetic reversal of greatest significance for global correlations" and to have been established and well dated in Canada, the North Atlantic and New Zealand and tentatively recognised in Czechoslovakia, the Northern Pacific, the Gulf of Mexico, Japan and France. Noël[4] has described further palaeomagnetic results from two Swedish varved-clay cores as accurately tracing the annual behaviour of the geomagnetic event and delimiting its initiation and termination. Recognition of the event in lavas and deep sea, continental shelf, varved-clay and lake sediments has been cited as confirming the reality of the event. That previous research, particularly in Sweden, has concentrated on palaeomagnetic measurements at numerous, different late Weichselian localities. Because of the difficulties in correlating between localities, interpreting palaeomagnetic records in coarse grained sediments and deciphering coring and sedimentological complexities in single cores, we have instead

studied one carefully selected site in detail. We have come to the conclusion that Swedish late Weichselian palaeomagnetic data do not record a reversal or excursion of the geomagnetic field, but demonstrate that the Swedish geomagnetic field has been of normal polarity since 13,000 yr BP. The Swedish late Weichselian reversal had thus become an example of Watkins'[5] "reinforcement syndrome".

We have analysed 408 subsamples from two main cores collected at Björkeröds Mosse on Mt Kullen in north-western Scania in southern Sweden (56.2°N, 12.6°E). Björkeröds Mosse was chosen because it lies in the area considered to be the earliest ice-free part of Sweden[6]; its stratigraphy, vegetational and soil developments have been studied in detail[7,8]; it had a high rate of deposition of organic sediments; and its chronology is well known from both pollen and radiocarbon dating[7]. The sediments from Björkeröds Mosse span the supposed age of the late Weichselian geomagnetic reversal of 12,400 or 12,100 yr BP. Ten sections of 'D'-shaped core, each 1 m in length, were obtained using a Jowsey sampler[9]. The natural remanent magnetisation (NRM) of the 408 subsamples was measured on a 'Digico' magnetometer[10]. Twenty-two pilot samples were partially a.c. demagnetised stepwise in increasing peak fields. A peak alternating field of 100 oersted was selected to eliminate viscous components. The remaining 386 subsamples were cleaned at this field strength. NRM, cleaned declination and inclination, cleaned intensity, and low field reversible susceptibility of core III (1975) are shown in Fig. 1.

We interpret the palaeomagnetic directions as follows. In general, the geomagnetic field close to the time of deposition is recorded by the palaeomagnetic remanence. At a few lithologically distinct horizons, however, the magnetic remanence has been controlled by other processes. The scattered or offset declinations and inclinations in the laminated deposits of layer 1 at depths of 615, 520 and 440 cm (Fig. 1) occur in coarser grained sediments and are due to rough alignment in higher energy deposition environment, rather than to idealised alignment along the ancient magnetic field direction. The single, reversed inclination at a depth of 338 cm (Fig. 1) falls in a narrow dark layer about 2 cm thick. A dark layer at a similar stratigraphic level in Björkeröds Mosse has been reported by Mörner in core B892 to be "well established" as a geomagnetic excursion and to correspond to his Fjards interstadial. The layer

Fig. 1 Data from Björkeröds Mosse core III (1975). ○, NRM; ●, partial demagnetisation at 100 oersted. Crosses indicate end of core sections. Mean declinations were set to zero.
in our core III (1975) is anomalous as, (1) its base is markedly (our results, in preparation) crenelated, (2) it does not occur in two other duplicate cores, and (3) the remanence is unusually stable as well as in a distinct direction. Its pollen spectrum and sediment chemistry correspond to the till which forms the banks of the lake. We prefer to interpret this intermediate palaeo-magnetic direction and Mörner's[11] in core B892 to be due to slumping rather than a true reflection of the geomagnetic field. The remaining great majority of palaeomagnetic directions are all of normal polarity and are taken to indicate that the geo-magnetic field was of normal polarity from 13,000 to 11,000 yr BP in Sweden.

The retention of aberrant magnetic directions and the between-core repeatability (our results, in preparation) of cleaned remanent intensity indicate that these normal polarity late Weichselian palaeomagnetic directions are almost con-temporary with deposition and are unlikely to have been caused by later remagnetisation. Our data suggest previously reported reversed palaeomagnetic directions[1 -4] are not reliable indicators of the ancient geomagnetic field, but have been distorted by mechanical sedimentation processes, slumping or weathering. Alternatively, but less likely, the reversed directions had been dated inaccurately. We suggest the proliferation of unusual palaeomagnetic directions in Scandinavia around 12,000 yr BP is a reflection of changing climatic conditions. In many localities the fluctuations of climate produced sediments of very variable mechanical properties, particularly at times of periglacial activity, which were poor recorders of the ambient magnetic field direction.

Using geomagnetic events in the Swedish late Weichselian is thus of doubtful value. Furthermore, reversals or excursions of the geomagnetic field from other parts of the world around this time should not be dated or correlated with the earlier Swedish results.

Watkins'[12] warnings on "the special problems posed by the search for short events" have unfortunately not been heeded. We endorse his comments[12] and on the basis of our work on the Swedish late Weichselian propose three minimum requirements for the recognition of geomagnetic excursions in recent sedi-ments: (1) both magnetic declination and inclination changes should be repeatable to within 20° in at least two sections or cores at the same site; (2) results should only be taken from macroscopically homogeneous lithologies with an average grain size below 62.5 µm; and (3) magnetic directions should be stable under alternating field cleaning with peak field ≥ 100 oersted.

Application of these criteria would prevent many spurious palaeomagnetic directions being interpreted as evidence for unusual geomagnetic behaviour. It would reduce the large number of excursions and events deduced from Brunhes sediments to a small total comparable to that recognised in igneous material[13]. It would also reduce the difficult dating problems arising from attempts to correlate recent excursions, dispel speculation[11] on very rapid changes in the main dipole field and enable geomagnetic excursions to be considered again as chronological indicators.

January-thaw singularity and wave climates along the Eastern coast of the USA

METEOROLOGICAL singularities—recurrent weather phenom-ena at or near specific calendar dates[1]—have been reported throughout the Northern Hemisphere. Although not fully recognised as real phenomena by most meteorologists, singularities continue to merit the attention of some investi-gators. Although the general relationship between wind fields over open oceans and generation of waves by wind are well known, there are no reports in the literature on coastal wave climates and atmospheric singularities. I have observed that extreme frequencies of surf from directions more typical of the summer season occur at the time of the 'January-thaw' meteorological singularity (January 20-23). Here I present observations of wave climates from Florida to Rhode Island at the time of the January thaw.

Slocum[2] recorded an anomalous warm spell during January 20-23, between 1872 and 1921. Subsequently, Wahl[3] demonstrated the existence of the January thaw in New England for the period 1873-1952 and Frederick[4] reported on its extensive geographical distribution between 1927 and 1956. Wahl[3] also noted that at the time of the January thaw the ridge-and-trough positioning over eastern North America differed markedly from its positioning before after-wards; specifically, during the January thaw there is a high pressure cell off the east coast of the USA, and a trough runs through the midwest, whereas immediately following the thaw, the positions of the ridge and trough are reversed. Anticyclonic singularities have been reported for Europe (January 18-24) by Brooks[5] and Japan (January 24) by Maejima[6].

Duquet[7] has attributed the January thaw to an adjust-ment of the planetary circulation occurring in early or mid January. Wahl[8] has noted that the January thaw is most pronounced during low-index Januaries. Significant changes in the general circulation of the atmosphere at the time of the January thaw are well documented. These changes should appear as a singularity in coastal wave-climate statistics.

Surf-height and direction statistics for years falling within a period of general low index[9] were obtained from the Co-operative Surf Observation Program (COSOP) for Point Judith, Rhode Island (1957-1965); Atlantic City, New Jersey (1955-1964); Ocean City, Maryland (1955-1970); Virginia Beach, Virginia (1954-1969); Oak Island, North Carolina (1955-1965); and Hillsboro Inlet, Florida (1955-1965), (Table 1). Daily and 3-d running means of surf heights were examined but did not show any anomalous characteristics at the time of the singularity; however, at the time of the January-thaw singularity, the directions of approaching surf along the Atlantic coast are atypical of winter. The magnitude of the departure from winter condi-tions to surf conditions more typical of summer are de-monstrated by the occurrence of extreme frequencies for various surf directions during the period of the singularity (Table 1). Although Wahl[3] has shown that the pressure field characteristic of the singularity is present on January 20, the maxima and minima of frequencies for each surf direc-tion generally occur around January 23. This apparent lag may be attributable to the required time of wave generation and travel to the coast.

*Minimum value for month of January.
†Maximum value for month of January.
‡Minimum value for year.
§Maximum value for year.

At Ocean City, Virginia Beach, and Hillsboro Inlet, surf from the south-east dominates. At Atlantic City extreme high frequencies of south surf occur, and at Point Judith surf from the south-west dominates. On Oak Island southerly and south-westerly surf dominates, and at Hillsboro Inlet north-easterly and south-easterly surf predominates. The hypothesis enunciated here is not supported only at Atlantic City where the 1% level-of-significance criterion was not met.

Duquet[7] has suggested that the January thaw is a manifestation of "an adjustment of the planetary circulation from what might be called an early winter stage to a late winter stage . . . " The statistics of south-easterly surf at Hillsboro Inlet support the season-transition concept. The period of October 1–January 20 is characterised by a mean frequency of south-easterly surf of about 9%. During the period January 20–end March, the mean frequency of surf from the south-east is 23%. Thus, the time progression of south-easterly surf at Hillsboro Inlet takes the form of step functions rather than of a monotonic sequence.

Coastal wave climates are traditionally viewed as a simple annual cycle between summer and winter conditions, and definition within the annual cycle is not generally recognised. If other atmospheric singularities are found to mark simultaneous changes in wave climates, then such information would have immediate application to coastal planning in general, and coastal engineering in particular. Further investigation of coastal wave climates should answer this question and may further clarify the many unanswered questions about atmospheric singularities.

Middle Pleistocene stratigraphy in southern East Anglia

A STUDY of Quaternary deposits in south-east Suffolk revealed a complex, and hitherto unrecognised Middle Pleistocene stratigraphic sequence[1]. The probable ages of the units in the sequence are, from the base upwards, river sands and gravels of Beestonian age, a rubified palaeosol of Cromerian age, and a periglacial palaeosol, loess, glacifluvial gravel, and till of Anglian age (Table 1). A preliminary survey of the Quaternary deposits in Essex has revealed a similar sequence. We here outline the main characteristics of this sequence, which has now been recognised over some 2,000 km² in southern East Anglia, and discuss its palaeoenvironmental significance.

The Beestonian sands and gravels are the most widespread Pleistocene deposit in the region. They form a body which trends south-west–north-east across the area (Fig. 1) and reaches a maximum observed thickness of 30 m. They are characteristically though not invariably a whitish colour, and are composed predominantly of flint and quartzite with small percentages of other rocks such as chert, rhyolite and tuff[2]. Far travelled materials such as Bunter quartzite, chert and volcanic rocks show that much of the deposit has been transported into the region, and the absence of non-durable material such as chalk, London Clay mudballs, and Jurassic shells and shale from the main body of the deposit suggests that the bulk of the material has been subjected to prolonged fluvial abrasion. North-eastward dipping large scale and small scale cross-set structures with occasional silt lenses indicate that the material was deposited as bars and dunes by a river with an irregular regime and a north-eastward direction of flow. Intraformational ice-wedge casts, vein-ice casts, and segregated ice accommodation structures are developed throughout the deposit, demonstrating that the fluvial processes operated in a periglacial environment.

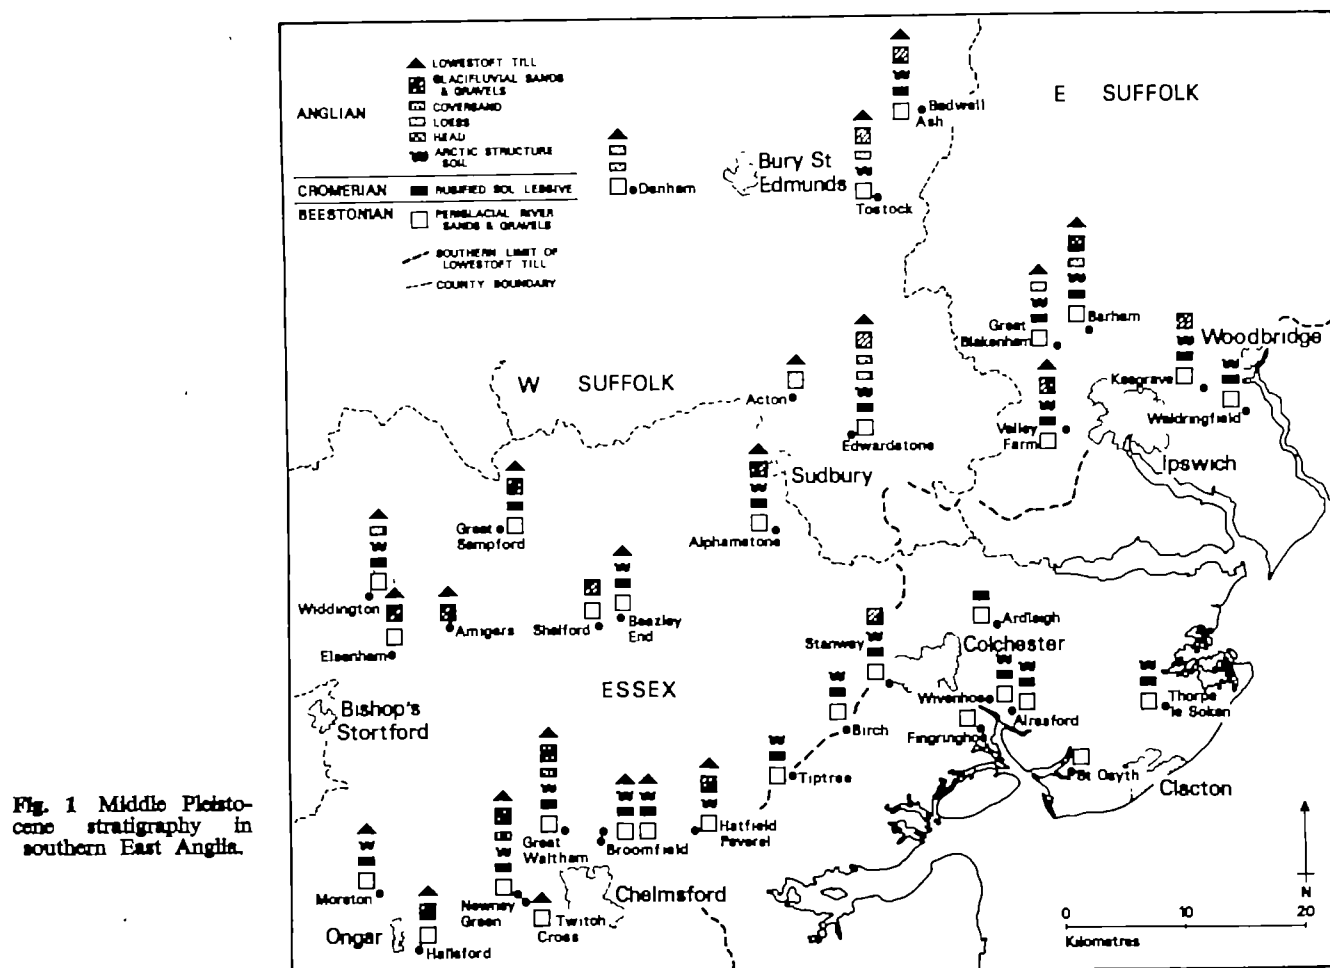
The height range of the surface of the deposit (Fig. 2) suggests that it is composite in origin, and may represent a series of river terraces formed at progressively lower levels as the river migrated south-eastwards. Considered in a regional context this body of sand and gravel probably


Fig. 1 Middle Pleistocene stratigraphy in southern East Anglia.

represents the debris of a much larger Thames drainage system, operating with a load and regime controlled by periglacial conditions.

These Beestonian sands and gravels were included by Prestwich[3] in his Westleton Beds which he considered to be marine in origin and separate from the glacial gravels. In contrast, Clayton[4] regarded all the sands and gravels of the Chelmsford and Harlow regions as glacial outwash, naming them the Danbury and Chelmsford Gravels, though Solomon[4] pointed out that the heavy mineral assemblage indicated that there were two separate units, one of which could not be associated with the local till. Bristow and Cox[5] also regarded these two gravels as glacial outwash but proposed that they both be called the Chelmsford Gravels.

The Cromerian palaeosol is a rubified *sol lessivé modaux*[6], and is developed on the surface of the Beestonian sands and gravels. Usually this soil is truncated, so that only the alluvial horizon survives in the form of a reddened zone associated with cutans, clay enrichment and iron enrichment. Soils of this type are produced in a humid warm

temperate climate[7,8], and as such reflect stable soil conditions which existed beneath the Cromerian mixed oak forest[9].

The Anglian palaeosol is an arctic structure soil[10], and is identified by involutions, frost cracks, and epigenetic ice-wedge casts which disturb the horizonation of the rubified *sol lessivé* and the primary structures in the upper part of the Beestonian sands and gravels. The loess that is developed in south-east Suffolk is represented by coversand in Essex (Fig. 1). The stratigraphic equivalence is demonstrated by a diagnostic heavy mineral assemblage (J. A. Catt, personal communication). Where both deposits exist at a site the coversand is uppermost. Their association with the arctic structure soil is shown by the fact that both deposits mix with the involutions and rest on the periglacial soil surface. At locations where the arctic structure soil has not been subsequently buried by the till, only the basal part of the ground ice structures remain, and the upper parts have been disturbed by younger periglacial activity.

The Anglian glacifluvial sands and gravels succeed the

Table 1 Middle Pleistocene stratigraphy and palaeoenvironments in southern East Anglia

Stage name	Formation name in south-east Suffolk	Environment	Sediments and palaeosols in Essex and west Suffolk
Anglian	Lowestoft Till	Glacial	Till (Lowestoft Till[11,15])

	Barham Loess Barham Arctic Structure Soil }	Periglacial	{ Loess and Coversand Head Arctic Structure Soil
Cromerian	Valley Farm Rubified *Sol Lessivé*	Humid, warm temperate	Rubified *sol lessivé*
Beestonian	Keagrave Sands and Gravels	Periglacial	Sands and Gravels (Essex White Ballast[8,11])

arctic structure soil. This deposit is only occasionally present beneath the till (Fig. 1), and beyond the till margin it is restricted to channels cut in underlying deposits. The base of the deposit is characterised by a pebble lag, but the main body consists of pale brown, well sorted sand and gravel composed predominantly of locally derived flint and quartzite (from the Beestonian sand and gravel) and a small component of glacially derived non-durable rocks. Primary sedimentary structures consist of small channels, plane beds, and small scale, tabular cross-sets which dip predominantly south-eastwards in Suffolk, and indicate that the deposit formed as dunes in shallow, braided rivers which drained away from the Lowestoft Till ice sheet in directions normal to the ice margin. Ground ice structures are absent from this deposit, and suggest that sedimentation rates were more rapid than the rate at which permafrost could develop. This deposit includes the upper part of the Chelmsford gravels[4].

Lowestoft Till of Anglian age[11,12] forms the upper part of the succession, and several of the sites have been studied by Perrin *et al.*[12]. At many locations the till rests directly on the undisturbed palaeosols or the wind-blown sediments. This indicates that over parts of southern East Anglia, glacial erosion did not occur, and probably suggests that flow tills protected the existing deposits before they were overridden by glacier ice.

The palaeoenvironmental significance of the Middle Pleistocene stratigraphic sequence in southern East Anglia can be summarised as follows:

(1) Two separate sand and gravel bodies can be recognised. The Beestonian river deposit is extensive throughout the region. The Anglian glacifluvial deposit is thin and localised. The earlier deposit is related to a north-eastward system of drainage. The present-day south-eastward and southward drainage patterns in the region were initiated during the Anglian glaciation with the deposition of the proglacial outwash.

(2) Downcutting and migration by the Thames drainage system began during the Beestonian periglacial stage, and by the time of the Cromerian Interglacial, the river must have adopted a route south and east of a line from Chelmsford to Colchester and Woodbridge (Fig. 2).

(3) The Cromerian rubified *sol lessivé* is developed widely across southern East Anglia. Where it is buried beneath Anglian glacigenic sediments it forms a clear stratigraphic horizon. Where it remains at the surface it forms the parent material for present-day soils which consequently have a reddened appearance.

(4) The Anglian arctic structure soil is developed across the region in association with loess and coversand. These aeolian deposits differ from Devensian aeolian sediments in their heavy mineral composition.

(5) Glacial erosion of pre-existing sediments and soils is negligible over large parts of the glacierised area of southern East Anglia.

Oldest recorded *in situ* tracheids

RECENT critical reviews[1] have suggested that evidence from microfossils[2] (that is spores with triradiate marks, sheets of "cells" or tubes with tracheid-like thickenings) should not be considered sufficient to demonstrate the existence of vascular plants in Silurian times; the only acceptable

Fig. 1 Terminal globose sporangium (×18).
Fig. 2 Two spores with gaping trilete marks isolated on film pull and photographed using infrared film ($\times$750).

Fig. 4 Unbranched carbonaceous stem from which tracheids in Fig. 5 were isolated ($\times$7).

evidence being megafossils with tracheids *in situ*. Such was the evidence presented by Lang[3] when he described smooth axes from the Downton Series (Pridolian $\varepsilon\beta_2$) of the Welsh Borderland. These vascularised axes were found in association with two species of *Cooksonia*, very simple plants with smooth forking axes terminating in globose sporangia which contained spores bearing trilete marks. Megafossils morphologically similar to *Cooksonia* have been described from strata of similar age throughout the world, but the Lang specimens are the only ones with unequivocal tracheids and thus have hitherto been considered the earliest vascular plants. We report here the occurrence of a vascular plant in the slightly older Whitcliffian strata (Ludlow Series) of South Wales.

Our investigations have centred on a lower Whitcliffian flora (uppermost Ludlow Series$\equiv$Kopaninan $\varepsilon\beta_1$) from the Capel Horeb Quarry, Powys (SN 844323); the age of the plant-bearing Roman Camp Beds being based on faunal[4] and microfossil evidence (personal communication from K. Dorning). Among smooth often dichotomously branching carbonaceous axes are a few *Cooksonia*-type sporangia (Fig. 1) some of which contain spores with trilete marks (Fig. 2). A central longitudinal line visible in some of the axes is presumed to represent conducting tissue[5], although until the study reported here tracheids have not been isolated from this region. Regular transverse banding reminiscent of tracheidal pitting (Fig. 3) is often observed, but there is a possibility that such a pattern has been produced by the

regular fracturing of the carbonaceous residues. This explanation, however, cannot be applied to the short lengths of tracheids recovered on a cellulose acetate film pull from an unbranched axis 10 mm long and 1 mm wide (Fig. 4). Figure 5 shows two, possibly three adjacent incomplete tracheids, partly masked by a darker, more opaque, noncellular layer. The longitudinal walls are 7.5 μm apart in the longest element and the horizontal bars are, on average, 5 μm apart. Although we are reluctant to draw any conclusions on the type of pitting from such fragmentary compression fossils, there is some resemblance to the annular thickening described by Lang in his Downtonian specimens.
Fig. 5 Fragments of two adjacent tracheids isolated on a film pull and photographed using infrared film. Arrow indicates longitudinal axis of stem ($\times$416).

Our findings therefore indicate the presence of vascular plants, most probably of *Cooksonia*-type organisation, in the upper part of the Ludlow Series, slightly older than the Downtonian vascularised axes of Lang.

Wild bank voles (*Clethrionomys glariolus*) are possibly a natural reservoir of campylobacters (microaerophilic vibrios)

STRAINS of *Campylobacter*, a genus of microaerophilic bacteria, have been isolated by various workers from the gut and faeces of several animal species including man[1], but as far as we know, there have been no reports of their isolation from rodents. The continuing importance of diseases of farm animals involving campylobacters, for example infectious infertility and sporadic abortion in cattle[2], abortion in sheep[2] and dysentery in pigs[3], and the paucity of information on the source of outbreaks of some of these diseases prompted us to investigate whether campylobacters were present in the faeces of bank voles (*Clethrionomys glariolus*), short tailed field voles (*Microtus agrestis*) and long tailed field mice (*Apodemus sylvaticus*) from their natural habitat. These species are common throughout mainland Great Britain[4] and were being trapped as part of an investigation into the distribution of pathogenic bacteria and viruses in small wild rodents. Bank voles and field mice are commonly found in woodland and scrub, and short tailed field voles are found in grassland, therefore all three species might provide a source of infection for domestic animals. We report here that bank voles carry campylobacters.

At intervals of 6 weeks during a period of 3 months bank voles and field mice were trapped in an area of mixed broadleaved woodland in Berkshire, and short tailed field voles were trapped in an area of well established grassland in Hampshire. The animals were caught in Longworth traps[5] arranged in a squared grid of 3,600 m² in each trapping area. Two traps were placed at each point, with an interstation distance of 10 m. A faecal pellet voided by each animal was placed in 5 ml of quarter strength Ringer's solution in a 0.5-ounce McCartney bottle, and maintained at 18–20 °C for not more than 3 h before selective culture for campylobacters on blood agar by a filtration method[1]. Isolation plates were examined after incubation in 30% (v/v) CO_2 in air for 4 d at 37 °C. If colonies of *Campylobacter* were not detected, the plates were reincubated and examined after a further 10 d.

We isolated bacteria which we identified as *Campylobacter* from the faeces of 10 out of 13 bank voles, but not from the faeces of any of 12 field mice or any of 17 short tailed field voles examined. *Campylobacter* isolates from bank voles were motile, Gram-negative, slender curved rods with a predominance of coccal forms in old (5 d) cultures. On blood agar after incubation for 3 d at 37 °C colonies were irregular, tending to spread. Each colony had an entire edge and was light grey with a diameter of 2–4 mm. All isolates produced catalase and reduced nitrate to nitrite, but did not produce acid in media containing glucose, grow in nutrient gelatin or haemolyse blood. They produced H_2S detectable by lead acetate paper only when grown in a medium with added cysteine[6]. Growth did not occur, or was very slow, in media containing 1% (v/v) glycine and in media incubated either in air or in anaerobic conditions. By these criteria our isolates resemble *C. fetus* ssp. *venerealis* biotype *intermedius*[6], a resemblance which is interesting since campylobacters with these characteristics have been recognised as a cause of infectious infertility in cattle[7].

Our work shows that animals hitherto not considered in studies on the epidemiology of diseases of domestic animals carry campylobacters and may provide a reservoir of infection. Furthermore, it is possible that *Clethrionomys glariolus* might provide what is much needed for research into campylobacter infections—a laboratory model for pathogenicity studies.

Population density affecting adult shell size of snail *Cepaea nemoralis* L.

THOMAS *et al.*[1,2] have questioned the ability of molluscs to limit their population size by self inhibition at high densities. They suggest that plant metabolites may have caused the reduction in growth and fecundity of the aquatic snail *Biomphalaria glabrata* Say ascribed to crowding in previous studies[3,4]. Field evidence for density-dependent regulation is limited. Yom-Tov[5] found that the fecundity of the desert snail *Trochoidea seetzeni* Pfeiffer was adversely affected by population density; he considered that either self-inhibition or nutritional differences were responsible. While studying the population dynamics and energetics of the land snail *Cepaea nemoralis* L., we have found evidence for density-dependent effects that cannot readily be explained by resource limitation. In samples of *C. nemoralis* collected in 1968 to study shell polymorphism (M. A. Palles-Clark, unpublished) a negative correlation was noticed between adult shell diameter and sample size ($r = -0.60$, $P < 0.001$). Snails were collected from chalk grassland between Beacon Hill and Round Down, West Sussex. A more detailed study carried out in the same area during the summer of 1973 confirmed this effect. The density of adult *C. nemoralis* was measured by mark-recapture at nine 20×20 m sites, situated 100–600 m apart. Each site was sampled in May, June and August. As there were insufficient recaptures to use multiple recapture methods for all sites, adult population densities were estimated for the second sampling occasion using the Lincoln index.

Measurement of adult shell diameter showed a 6–9% decrease in adult size associated with an increase in density from 0.5 to 5.5 adults per m² (Fig. 1). The pattern of population density was patchy but similar to that found in 1968. There were no simple relationships between density and geographical features, for example altitude or aspect. There were slight differences in shell colour and banding morph frequencies between the sites but these did not relate to differences in adult density or shell size.

Figure 1 also shows changes in mean shell diameter with season, reflecting a change in age structure of the adult population. Separate values of shell diameter are given for May, when the collections were mostly of old adults, surviving from previous years, and for August, when new adults (with shiny shells, periostracum intact) predominated. The August results exclude snails captured and marked in either May or June. Snails were considered adult when a lip had been formed at the mouth of the shell; after lip formation there is no further increase in shell diameter. Regression lines drawn through each set of data had significantly different slopes ($P < 0.02$), the change in slope indicating that recruitment to the low density populations increased mean adult size, whereas recruitment to the high density populations had the opposite effect. Long term
Fig. 1 Relationship of mean adult shell diameter ($\pm$s.e.) and adult population density. ●, Samples collected on May 23, $Y = 21.19 - 0.238X$ (s.e. slope $= 0.038$); ○, samples collected on August 7, $Y = 21.56 - 0.382X$ (s.e. slope $= 0.034$).

studies at an adjacent site did not show any significant changes in adult shell diameter over autumn and winter. It therefore seems that the differences between new and old adults are a function of the conditions experienced by juveniles, rather than selection pressures operating on adults. Unfortunately our field data do not enable us to separate the effects of juvenile and adult population densities on juvenile growth rates, nor to determine the time when growth is most affected.

The decrease in shell diameter with increasing density has a marked effect on body weight, reducing it by 14–31% (values determined from log–log regressions of weight and size for new and old adults[6]). Wolda's studies[7], in field conditions and in the laboratory, indicate that fecundity would be similarly reduced. His regressions relating shell diameter to clutch size and oviposition frequency for *C. nemoralis* predict a 22% decrease in annual egg production when adult shell diameter changes from 21.2 mm to 19.3 mm. Overwinter survival could also be affected: Cook and O'Donald[8] found that smaller adult *C. nemoralis* from a Pyrenean population were at a selective disadvantage when kept in experimental conditions producing high mortalities during dormancy.

A similar relationship between shell size and population density was detected by further analysis of Wolda's[9] field data. When adult shell diameter was plotted against density index the regression slope was negative and significantly different from zero ($P < 0.001$, combined data from east–west and north–south roads). Wolda's sampling sites were distributed over a total area similar to ours (about 0.5 km^2). Over larger areas, the variation in other factors affecting shell size, for example calcium availability, would be increased; consequently we would not expect the effect of population density to be so marked.

There was no indication that *C. nemoralis* at our study area was limited by either food quantity or quality. Point quadrat surveys of the nine sites did not show any correlation between population density and the vegetation biomass, nor between density and the proportion of palatable plants in the standing crop (R.A.D.C., P.W. and D. I. Morgan-Huws, unpublished). The feeding of *C. nemoralis* was studied in detail for a population with a

density of five adults per m^2 in June 1973, and a mean annual biomass (March 1973–March 1974) of 1.03 g m^{-2} for adults and juveniles. It was estimated[10] that this population consumed 3.7% of the above-ground production of herbs, 0.6% of that of grasses, and 0.91% of the total above-ground primary production. Preferred foods (dead herbs) were available at all times of the year. Calcium deficiencies were most unlikely: at all sites pieces of chalk were present at or near the soil surface. Shells of dead snails provided an alternative supply.

We therefore conclude that interactions between snails, either chemical or behavioural, were responsible for slowing juvenile growth rates in high density populations, resulting in smaller adults, and thus affecting the birth rate in succeeding years. It is likely that the changes in adult shell size that occurred in Wolda's field[9] and experimental[11] populations of *C. nemoralis* were caused by similar density-dependent effects. Laboratory studies are in progress to determine the effect of density on juvenile growth in experimental conditions. Initial results show that the presence of mucus trails of other snails inhibits activity, suggesting a possible mechanism for the effects observed in the field.

Overdominance and U-shaped gene frequency distributions

A GENERAL pattern that emerges from electrophoretic analyses of protein variation in natural populations is that alleles with intermediate frequencies are rare. This results, graphically, in a U-shaped frequency distribution when both allele frequencies from a two-allele locus are plotted. Supporters of the neutralist theory of population variation believe that most protein polymorphisms found in nature are the result of the random drift of neutral mutations and argue that a U-shaped distribution is expected for the case $4Ns < 1$, where N is the population size of diploid organisms and s is the average selection coefficient. We show here that, under certain assumptions, a U-shaped frequency distribution also obtains when $4Ns > 1$. From this we conclude that the analysis of allele frequency distributions (or, equivalently, relative contributions to heterozygosity) does not provide a sensitive means of resolving the neutralist and selectionist controversy.

In the textbook model of an overdominant polymorphism, two alleles, A and B, segregate at a locus, the frequency of allele A indicated by $\hat{p}$ and the genotypes AA, AB and BB have relative fitnesses $1 - s_1$, 1 and $1 - s_2$, respectively, where

$0 < s < 1$. It is easily shown that the equilibrium frequency of A, denoted $\hat{p}$, is $s_2/(s_1 + s_2)$. Various biochemical, physiological, genetic and ecological mechanisms can account for the relative superiority of the heterozygote. Our approach will specify the distribution of $\hat{p}$, given certain assumptions about the distributions of s_1 and s_2. We begin by postulating that s_1 and s_2 are independent, and will discuss the possibility of positive or negative correlation later.

The probability distribution of selection coefficients, $g(s)$, defined on the interval $0 < s < 1$, gives the probability that a selection coefficient will lie between s and $(s + ds)$. We assume a single parameter family of such distributions, where b is a parameter that reflects different biological reality (see below)

$$g(s) = \frac{1}{b} s^{[(1/b)-1]} \tag{1}$$

We now seek the probability distribution for equilibrium gene frequency, $h(\hat{p})$, given that both s_1 and s_2 are distributed according to equation (1). We define two new variables

$$x_1 = s_1/(s_1 + s_2) \tag{2a}$$
$$x_2 = s_1 + s_2 \tag{2b}$$

Solving for s_1 and s_2 gives

$$s_1 = x_1 x_2 \tag{3a}$$
$$s_2 = x_2(1 - x_1) \tag{3b}$$

The Jacobian of transformation (3), that is, the determinate of $\partial s_i / \partial x_j$, is x_2, thus the joint probability distribution of x_1 and x_2 is

$$H(x_1, x_2) = \left[\frac{1}{b}(x_1 x_2)^{[(1/b)-1]}\right]\left[\frac{1}{b}(x_2(1-x_1))^{[(1/b)-1]}\right]x_2 \tag{4}$$

Since x_1 and x_2 can be separated

$$H(x_1, x_2) = \frac{x_2^{[(2/b)-1]}}{b^2}(x_1(1-x_1))^{[(1/b)-1]} \tag{5}$$

It is then possible to obtain the marginal probability distribution of x_1, $h(x_1)$, by integrating over x_2 in the domain of the distribution of distribution function H ($0 \leq x_2 \leq 1, 0 \leq x_1 \leq \min(1/x_2, 1 - [1/x_2])$), yielding

$$h(x_1) = \begin{cases} x_1^{[(1/b)-1]}(1-x_1)^{[(-1/b)-1]}/(2b), & 0 \leq x_1 \leq 0.5 \tag{6a} \\ x_1^{[(-1/b)-1]}(1-x_1)^{[(1/b)-1]}/(2b), & 0.5 \leq x_1 \leq 1 \tag{6b} \end{cases}$$

This distribution, symmetrical about 0.5, gives the probability of $1 - \hat{p}$ ($= \hat{p}$) if s_1 and s_2 are taken from probability distribution equation (1). Functions $g(s)$ are plotted in Fig. 1A for different values of b, with the corresponding $h(\hat{p})$ distributions plotted in Fig. 1B. The question remaining is which, if any, values of b correspond to biological reality.

Although a fairly high percentage of newly arisen mutations may be lethal, most of the alleles persisting at a locus in a natural population are not seriously deleterious as homozygotes: really deleterious genes will be eliminated soon after they appear. Thus it is reasonable to postulate that homozygotes that persist in a population will have fitness nearly equal to the heterozygote and that the mode of the distribution $g(s)$ will be at $s = 0$, with the probability of larger s falling off rapidly with increasing s. This corresponds to large values of b, which give U-shaped gene frequency distributions.

As mentioned, we have assumed that s values are uncorrelated. A negative correlation, which pairs large and small s values,
Fig. 1 *A*, Some $g(s)$ distributions for different values of the parameter b, the numerical value of which is given above the line. *B*, Some $h(\hat{p})$ distributions for the same five values of parameter b. The heavy line is a hypothetical distribution for which all values of $\hat{p}$ are equally likely.

seems to us absurd; it would, however, increase the tendency towards U-shaped gene frequency distributions. Positive correlations between s values work against U-shaped distributions. A likely source of such a positive correlation is a situation where the selection coefficients for the homozygotes at some 'important' loci tend to be high, whereas those for other 'less important' loci tend to be low. We admit that some loci are more essential than others, but alleles persisting in natural populations at such relatively essential loci cannot deviate far from optimal functioning before the s values become large. Conversely, populations seem to tolerate a much broader range of function at loci which *a priori* are less critical metabolically. For example, an $s = 0.5$ might correspond to a very slight biochemical change in a regulatory enzyme on the one hand, and to a virtual absence of function of a coat colour gene on the other. We feel therefore, that it is incorrect to equate physiological or developmental importance with the effect of a locus on fitness. Rather, it is reasonable that the s distributions for all types of loci are the same and that our assumption that the individual s values at a locus are uncorrelated is warranted.

This result is not solely dependent on equation (1). We have used other single parameter probability distributions for $g(s)$. One family of functions was

$$g(s) = b(1 - s^b)/(b + 1) \tag{7}$$

We were not able to obtain $h(p)$ analytically for this function, so we used numerical integration on a computer. Distributions of $g(s)$ which were concave towards the origin (corresponding to values of b in equation (7) less than 1) gave U-shaped distributions for the equilibrium gene frequency. In addition, we treated other $g(s)$ distributions in a Monte Carlo fashion and arrived at the same conclusion. If the natural distribution of selection coefficients is concave towards the origin, then U-shaped probability distributions of gene frequencies are to be expected.

Using equation (1) we have performed Monte Carlo simulation for more than two alleles at a locus. For tri-allele systems,

where the gene frequencies of the population can be represented as the three distances from the sides to an interior point in an equilateral triangle, the probability distribution for the equilibrium surface can be plotted as a surface above the triangular domain. Values of b that give U-shaped gene frequency distributions for two-allele cases give three-allele gene frequency distributions that have modes in the three corners and very low probabilities in the centre of the triangular domain. The same is true for four or more alleles.

The foregoing results apply to infinite populations. The situation for finite populations, where some sampling error (drift) is unavoidable, can be sketched. Robertson[1] introduced the idea of a retardation factor, which shows the strength of an overdominant polymorphism for slowing fixation. This depends on both the size of a population and on the deterministic frequency of equilibrium. For population sizes greater than 1,000, equilibrium frequencies in the range 0.2–0.8 are quite secure—the mean time to fixation is very long. When the equilibrium frequency is near 0 or 1, however, the rate of fixation may be even faster than for a purely neutral case.

By tending to fix those equilibrium frequencies in the ranges 0.05–0.20 and 0.80–0.95, such drift would change the A-shaped distributions in Fig. 1B to W-shaped distributions. It would also tend to square off the corners of a U-shaped distribution, but it would be impossible statistically to distinguish the two cases. Therefore, if our arguments are correct, gene frequency data cannot be used to determine whether most electrophoretic polymorphisms are neutral or selected.

Yamazaki and Maruyama[2] concluded that gene frequency data, in the form of contribution to relative heterozygosity, was inconsistent with the overdominant model. But this conclusion was based on the assumption that all equilibrium frequencies of overdominant polymorphisms are equally probable (corresponding to the heavy horizontal line in Fig. 1B); whereas, following the reasoning outlined in this paper, we believe that this assumption is not reasonable and that their conclusion is unwarranted.

We have not explained the phenomenon of the U-shaped allele frequency distribution. We have merely shown that it may be consistent with a selectionist model.

Triploid pseudogamous biotype of the leafhopper *Muellerianella fairmairei*

THE sibling leafhopper species *Muellerianella fairmairei* (Perris, 1857) and *M. brevipennis* (Boheman, 1847) (Homoptera, Delphacidae) are widely sympatric in Europe. Studies of the biological differences between the two species, and of their hybridisation has revealed a remarkably high proportion of females of *M. fairmairei* sampled in the field and a gradual disappearance of males in laboratory colonies. *M. brevipennis* had a normal sex ratio in field samples and when reared in the laboratory[1]. Additional cytogenetic studies now demonstrate that in *M. fairmairei* a pseudogamous female triploid biotype coexists with the diploid bisexual form.

Populations of *M. fairmairei* (Southern Greece and Southern France) and *M. brevipennis* (Holland), which maintain a 1:1 sex ratio are diploid ($2n = 28$). In both species the male

karyotype consists of thirteen autosome pairs and one XY pair ($2n = 13$ AII + XY). The female karyotype (Fig. 1a and b) shows thirteen autosome pairs and a large pair of XX chromosomes ($2n = 13$ AII + XX).

Populations of *M. fairmairei* from Holland (Leersum) and England (Ascot–Silwood Park) with a high proportion (75–100%) of females seemed to comprise diploid males and a mixture of diploid and triploid females. Somatic metaphases of the triploid females, as far as could be determined, consistently had 41 chromosomes, including three X chromosomes. Ovarian semi-mature and mature eggs always contained a metaphase plate with 41 "pseudobivalents" (Fig. 1c). Their size was approximately half that of the bivalents of the diploid female, and they resembled secondary oocyte chromosomes. In this insect the first and second meiotic divisions probably do not take place and are replaced by a single equational division.

After the triploid biotype of *M. fairmairei* had been isolated in the laboratory, three experimental crosses were made to investigate the role of the sperm in the production of triploid females. When the cross was *M. fairmairei* (3n) ♀♀ × *M. fairmairei* ♂♂, five pairs reared on their host plant, *Holcus lanatus* (L.) produced triploid females only and in high numbers (160–514) females per pair. All five females appeared to have mobile sperm in their spermathecae. When the cross was *M. fairmairei* (3n)♀♀ × *M. brevipennis* ♂♂, six pairs placed in a cage containing *H. lanatus* and *Deschampsia caespitosa* (L.) (the latter is the specific food plant of *M. brevipennis*) produced comparatively few triploid females (a total of 88). Three of the six crossed females had mobile sperm in their spermathecae. When the cross was *M. fairmairei* (3n)♀♀ × sterile hybrid ♂♂, nine sterile males (produced by previous crossing of *M. brevipennis* (2n)♀♀ × *M. fairmairei* ♂♂) were paired with females in glass tubes containing *H. lanatus*. Although the triploid females

Fig. 1 The chromosome complements of *M. fairmairei* (2n): a, *M. brevipennis*; b, *M. fairmairei* (3n); c, at the first female meiotic division, which occurs in the nucleus of semi-mature eggs. The bar in (c) represents 10 µm. All photomicrographs are reproduced at the same magnification.
were observed several times copulating with the hybrid males, none of the 163 eggs deposited exhibited embryogenesis.

Thus the triploid biotype of *M. fairmairei*, which is morphologically indistinguishable from the diploid female, has a typically pseudogamous mode of reproduction. The entrance of sperm (derived from the males of *M. fairmairei* or the closely related *M. brevipennis*) is necessary for embryonic development to occur, but the sperm probably do not fuse with the egg nucleus. Copulation with sterile males is ineffective. So far this mode of reproduction has not been reported in Hemiptera[2], although other forms of parthenogenesis are well known in this order.

When both female biotypes of *M. fairmairei* were reared together in the presence of males, the diploid type disappeared after one or two generations. The higher fecundity of the pseudogamous biotype and the fact that it produces all-female progeny possibly explain this phenomenon. It is not known how both biotypes can coexist in the field. It is clear, however, that the triploid type requires the availability of a diploid population for its maintenance.

An indication that the triploid biotype might be of hybrid origin is its ability to oviposit and develop on *D. caespitosa*, the host plant of *M. brevipennis*. Diploid hybrids, originated from crosses of *M. fairmairei* $(2n)$♀♀ $\times$ *M. brevipennis* ♂♂ and the reciprocal cross, have the same ability. Also, the meiotic behaviour of some female diploid hybrids (28 "pseudobivalents") closely resembles that of the triploid.

I thank Professor J. van der Veen and Drs J. Sybenga, R. H. Cobben and J. Gut for discussions.

Somatic hybridisation of *Petunia hybrida* and *P. parodii*

INTRASPECIFIC and interspecific fusion of plant protoplasts is induced by agents[1-4]. Protoplasts of several species can regenerate a cell wall and divide to form callus, from which whole plants can be grown[5]. To combine these processes and obtain hybrid cells and then hybrid plants several requirements must be met[6]. The parental protoplasts should be capable of being cultured, as should the hybrid cells, and plant regeneration must be possible. Selection procedures developed so far[7-10] may not be generally applicable, and we have now developed a method which makes use of naturally occurring differences in the sensitivity of cultured plant protoplasts to growth media and drugs[11].

One half of our selection procedure was based on a difference in growth between leaf protoplasts of *Petunia hybrida* and *P. parodii*. Protoplasts of *P. parodii*[12] never grow beyond the small colony stage (about 50 cells) in a medium similar to that of Murashige and Skoog[13] (M/S medium) while protoplasts of *P. hybrida* cultivar Comanche[14] produced callus[15]. The other half of the selection procedure was based on a difference in sensitivity to actinomycin D, *P. hybrida* protoplasts being more sensitive than those of *P. parodii*. The selection procedure is shown in Fig. 1.

Leaf protoplasts of *P. parodii* and *P. hybrida* were suspended in 9% (w/v) mannitol solution containing inorganic salts[17] (2×10^5 protoplasts per ml) and dispensed into screw-capped tubes in 8-ml volumes so that there was a viability control, and a fusion viability control for each species. A mixture of equal volumes of each species was used for the fusion treatment.

All tubes, except viability controls, were centrifuged (80*g*,

10 min) and the supernatant was removed. To each tube was added 2 ml of 15% (w/v) polyethylene glycol (Koch-Light, molecular weight 6,000), 4% (w/v) sucrose and 0.01 M CaCl₂ to induce fusion. Protoplasts were resuspended, left for 10 min at 25 °C and then gradually diluted by the addition, at 5-min intervals, of the M/S medium in volumes of 0.5 ml, 1.0 ml, 2.0 ml, 2.0 ml, 3.0 ml and then 4.0 ml. Protoplasts were resuspended after each addition. After centrifugation at 60*g* for 15 min, the supernatant was replaced by M/S medium (8 ml per tube). At this stage the two viability controls were centrifuged and the protoplasts were resuspended in M/S medium. A further control was prepared by mixing equal volumes of *P. parodii* and *P. hybrida* fusion viability controls (post-fusion mixture control). All tubes were left for 1 h before plating. On average 4% of the protoplast population had fused as determined by counts of nuclei.

Protoplasts were maintained in liquid medium by the liquid-on-agar culture method[15]. To each 9-cm plastic Petri dish was added 8 ml of M/S medium containing actinomycin D (1.0 µg ml⁻¹), solidified with 0.5% (w/v) agar. To the surface of the agar was added 4 ml of M/S medium, containing actinomycin D (2.0 µg ml⁻¹), plus 4 ml of the appropriate protoplast suspension (at 2.0×10^5 protoplasts per ml), in M/S meduim without actinomycin D so that the final concentration of the drug in the liquid layer was 1.0 µg ml⁻¹, with a protoplast density of 1×10^5 per ml. Protoplasts of the two viability controls were plated in M/S medium without actinomycin D, as were samples of the *P. parodii* and *P. hybrida* fusion controls. Dishes were maintained at 27 °C with continuous illumination of 1,000 lx from daylight fluorescent tubes.

After 28 d, colonies were transferred to dishes containing M/S medium with 3% (w/v) mannitol solidified with 1% (w/v) agar and no actinomycin D. Growing colonies were transferred finally after 60 d to M/S medium containing no mannitol. Colonies were also recovered from the *P. hybrida* fusion control, maintained in the absence of actinomycin D, and from the *P. parodii/P. hybrida* fusion treatment in the presence of actinomycin D. All other dishes were devoid of colonies except the *P. hybrida* viability control. After a further 10 weeks, the small calluses of the *P. parodii/P. hybrida* fusion treatment, and the *P. hybrida* fusion control, were transferred to M/S medium, containing IAA (2.0 µg ml⁻¹) and 6-benzylaminopurine (1.0 µg ml⁻¹), for plant regeneration. Ten calluses of separate origin were recovered from the *P. parodii/P. hybrida* fusion treatment. Of these, eight produced shoots on this medium. Subsequently they were removed and rooted in M/S medium containing NAA (0.1 µg ml⁻¹) as the sole growth regulator and 0.3% agar. Plantlets thus produced were potted and grown up to flowering. Callus from the *P. hybrida* fusion control did not regenerate shoots on the same medium, although some shoots were produced when zeatin (1.0 µg ml⁻¹) was added.

No plants of *P. parodii* were recovered since the protoplasts did not grow beyond the colony stage. Plants produced from the *P. hybrida* fusion control were all diploid ($2n = 14$), red flowered and like the parent species. All plants produced from *P. parodii/P. hybrida* fusion were purple flowered, and thus distinguishable from the parents (Fig. 2). Chromosome counts on roots showed a minimum number of 24, and a maximum of 28 in these plants.

Seedlings of *P. parodii* and *P. hybrida* were treated with colchicine (0.3% (w/v) aqueous solution) for 90 min to produce tetraploid ($4n = 28$) plants. The F₁ sexual hybrid (*P. hybrida* $\times$ *P. parodii*) was obtained at the tetraploid level using colchicine. The reciprocal cross (*P. parodii* $\times$ *P. hybrida*) was identical in all respects. As Fig. 2 shows, flowers of the plants with 28 chromosomes, produced by fusion, were very similar to those of the tetraploid F₁ sexual hybrid. Tetraploid *P. parodii* and *P. hybrida* parents were

Fig. 1 Selection scheme for the production of somatic hybrids of *P. parodii* and *P. hybrida* based on differential parental protoplast growth responses to M/S medium and actinomycin D. Both species gave high yields of protoplasts (2–3×10^6 per g fresh weight) with plating efficiencies of up to 40% in M/S medium, with naphthalene acetic acid (NAA) (2.0 μg ml⁻¹), 6-benzylaminopurine (6-BAP) (0.5 μg ml⁻¹), sucrose (3%) (w/v) and mannitol (9%) (w/v), pH 5.8. Division of *P. hybrida* protoplasts was limited by actinomycin D at 0.75–1.0 μg ml⁻¹ in M/S medium, yet protoplasts of *P. parodii* were not affected up to 5.0 μg ml⁻¹. In animal cells, actinomycin D resistance is dominant[16], and likely also to be so in *Petunia*. Callus of *P. parodii*[12] readily undergoes shoot formation, yet that of *P. hybrida* does not[15]. It was expected that the regeneration potential of somatic hybrids would be provided by the *P. parodii* genome. In M/S medium plus actinomycin D protoplasts of *P. hybrida* would be expected to remain alive, but not divide while protoplasts of *P. parodii* would divide to the small colony stage. If complementation occurs in the somatic hybrid, the *P. hybrida* genome would permit division beyond the colony stage, while the *P. parodii* genome would confer resistance to actinomycin D. Protoplasts did not cross feed with respect to the M/S medium and actinomycin D growth responses.

easily distinguished from the F_1 sexual hybrid and the regenerated plants, for doubling of the chromosomes in the parents affected neither flower colour nor morphology. Therefore, the plants resulting from fusion that had 28 chromosomes were classed as somatic hybrids (*P. hybrida* + *P. parodii*). The sexual hybrid ($4n$) and the somatic hybrid (28 chromosomes) were both self-fertile and cross-fertile.

Determination of leaf isoperoxidase showed that the somatic hybrids had the spectrum of bands associated with both parents (diploid and tetraploid); and 20% of stained gels had an extra faint band found also in the tetraploid F_1 sexual hybrid (Fig. 3). The presence of this additional band, coupled with the hybrid nature of the flowers excludes the possibility that a chimaera had been obtained.

Fraction 1 proteins of *P. hybrida* and *P. parodii* were purified and analysed by A. A. Gatenby in our laboratory, using a specific immunoabsorbent, as described before[18]. Preliminary isoelectric focusing experiments of S-carboxy-methylated protein, in the presence of 8 M urea, have revealed an identical polypeptide composition of the chloroplast-coded large subunit for both species. The small nucleus-coded subunit of *P. hybrida* contains two polypeptides[19]. *P. parodii* also contains two nucleus-coded polypeptides, both with isoelectric points identical to those found in *P. hybrida*. This is perhaps expected, for within the genus *Petunia* there seems to be a high degree of chromosome homology[20,21].

Experiments based on the same selection principle, and culture procedure, but with different concentrations of actinomycin D, have given selected calluses. Somatic hybrid plants have been produced after selection in M/S medium

Fig. 2 Flowers of (from top to bottom) tetraploid *P. parodii* (white), tetraploid F_1 hybrid (*P. hybrida* × *P. parodii*) (purple), somatic hybrid (28 chromosomes) (purple) and tetraploid *P. hybrida* (red). The purple flower colour corresponds to *Fuschia* purple (BCC No. 199, 28/1) and the red corresponds to Turkey red (Horticultural Colour Chart, 721). The somatic hybrid was also distinguishable from either of the parents on the basis of corolla tube and peduncle length. Petals of tetraploid *P. hybrida* were fringed, yet those of the F_1 hybrid and the somatic hybrid were smooth. Abaxial vein pigmentation of the floral bud was pronounced only in the F_1 hybrid and the somatic hybrid. Pollen of both parents was yellow, whereas that of the F_1 and somatic hybrids was occasionally purple.

Fig. 3 Diagram of starch gel electrophoresis of peroxidase isoenzymes from leaf material of: *a*, *P. hybrida* (4*n*); *b*, *P. parodii* (4*n*); *c*, *P. hybrida* (4*n*) and *P. parodii* (4*n*) mixed before homogenisation; *d*, *P. hybrida* × *P. parodii* (4*n*); *e*, somatic hybrid (*P. hybrida* + *P. parodii*) (28 chromosomes). Leaf material was homogenised in 0.2 M sodium chloride solution at 4 °C using 1 g fresh weight of leaf per 0.5 ml of solution. A sample of the fresh homogenate was absorbed into a filter paper wick which was inserted into a freshly made 10% (w/v) starch horizontal slab gel (Electrostarch). The gel buffer contained 90% (v/v) 0.01 M citric acid and 0.065 M Trizma base, *p*H 8.2, plus 10% (v/v) 0.025 M lithium hydroxide and 0.2 M boric acid *p*H 7.9. The tank contained only the latter buffer. After electrophoresis for 6 h at 4 °C (40 mA), the gel was sliced horizontally, and a lower slice was stained for peroxidases using 100 mg of *O*-dianisidine in 70 ml of 95% (v/v) ethanol, plus 28 ml of acetate buffer and 2 ml of 3% (w/v) hydrogen peroxide solution. (The acetate buffer contained 0.14 M sodium acetate and 0.06 M acetic acid.) Staining was conducted at room temperature for 45–60 min, followed by washing in 70% (v/v) ethanol; photographed, and R_f values recorded. ★, Position of additional band.

with actinomycin D at 0.9 µg ml⁻¹, 0.8 µg ml⁻¹ and 0.75 µg ml⁻¹. At 0.75 µg ml⁻¹ the selection conditions allow some *P. hybrida* callus to grow through. In these circumstances, somatic hybrids were preferentially recovered since the shoot-inducing medium only rarely supports shoot formation in *P. hybrida*. So far, four separate experiments have produced somatic hybrid plants. Calluses have been selected in each of two further experiments. These calluses have regenerated shoots but have not yet been analysed fully. In one experiment which produced no somatic hybrids, actinomycin D (2.0 µg ml⁻¹) was added 10 d after fusion treatment, and *P. hybrida* was not sensitive to this concentration at the colony stage, and in the presence of *P. parodii*.

The frequency of somatic hybrid plant formation was variable but was of the order of one in 1–8 × 10⁵ protoplasts. This does not take into account loss of protoplast viability

on plating or losses due to the effect of the fusion treament.

Because neither mutant nor haploid plants are required, this selection strategy should be readily applicable to a wide range of species. We are investigating—using this complementation-selection procedure based on naturally occurring differences between species—the consequences of fusion of protoplasts isolated from sexually incompatible species.

Pea root nodules containing more than one *Rhizobium* species

PARTICULAR species of legume are nodulated only by appropriate species of *Rhizobium*. Thus *R. leguminosarum*, *R. phaseoli* and *R. trifolii* nodulate peas, French beans and clover, respectively. The basis of this specificity between the two partners of the symbiosis is not understood. Complete specificity is not always found, however. Although *R. trifolii* does not normally nodulate peas, induced mutants of this species able to nodulate this host have been described[1] and some strains of *Rhizobium* isolated from clover nodules nodulated both clover and peas[2]. Selected clover lines have been nodulated by *R. leguminosarum*[3]. It has been reported that a non-rhizobial contaminant can occur in soybean nodules[4] and that the presence of *R. trifolii* may allow *R. meliloti* to occupy clover root nodules (B. O. Gillberg, personal communication). We show here that the presence of *R. leguminosarum* can allow *R. trifolii* and *R. phaseoli* to enter pea nodules but that *R. trifolii* cannot fix nitrogen in the nodules of this 'foreign' host.

The strains of *R. trifolii* (6001 and 6100) and *R. phaseoli* (1233) we used did not normally nodulate peas in our conditions. Of 15 plants inoculated with strain 1233 and 43 with strain 6001 none had any nodules, while one out of 36

plants inoculated with R. trifolii strain 6100 had three very small ineffective nodules. Since no viable bacteria could be isolated from them after surface sterilisation, strain 6100 could not be identified; conceivably they arose by contamination. The R. trifolii and R. phaseoli strains effectively nodulated clover and French bean plants, respectively.

The results of inoculating peas with various strains of R. leguminosarum together with R. trifolii or R. phaseoli are shown in Table 1. For each mixed inoculum at least one nodule on at least half of the plants contained the heterologous species. The frequency of such nodules was 2–27%. All nodules occupied by R. trifolii or R. phaseoli also contained the appropriate strain of R. leguminosarum. In most mixed nodules the heterologous species represented the minority of the bacteria recovered, but in some there were many more R. trifolii than R. leguminosarum. For example, from a nodule on a plant inoculated with strains 6100 plus 6099, 2.8×10^8 R trifolii and 2.2×10^2 R. leguminosarum were recovered.

For all mixed inoculations of R. trifolii plus ineffective strains of R. leguminosarum there was no nitrogen fixation as determined by the absence of acetylene reduction whether R. trifolii was the majority or minority strain. Four of the R. leguminosarum strains (6009, 6099, 7111 and 7112) were derived from single mutagenic treatments from effective parents and thus can be assumed to be defective in one or very few steps. It is apparent that the defect(s) in these strains and of the two ineffective field isolates of R. leguminosarum (922 and 983) could not be overcome by the R. trifolii strains Strain 922 dies not inhibit acetylene reduction when it occurs in the same pea nodule as an effective strain of R. leguminosarum[1].

A limited number of white clover (Trifolium pratense) plants was inoculated with R. trifolii strain 6001 plus R. leguminosarum strain 922 (which did not nodulate clover on its own). Of six nodules obtained from two plants, one contained both 922 and 6001. All six nodules were pink and effective, confirming that the presence of strain 922 in nodules did not inhibit nitrogen fixation by effective strains. This also demonstrates that occupation of nodules by heterologous species of Rhizobium is not restricted to peas.

Two independent R. leguminosarum strains (6007 and 6008) unable to nodulate peas were derived after ultraviolet

treatment of an effective strain (897). To determine whether the presence of non-infective strains of R leguminosarum would enable R. trifolii to occupy pea nodules, peas were inoculated with R. trifolii (strain 6001) plus strains 6007 or 6008; no nodules were formed. Strains 6007 or 6008 do not inhibit nodulation by effective strains of R. leguminosarum. Neither of these strains was recovered from any of 237 nodules from plants inoculated with nodulating strains of R. leguminosarum plus strains 6007 or 6008. It is perhaps surprising that the presence of an infective strain of R. leguminosarum does not allow non-infective mutants of R. leguminosarum to enter pea nodules but does permit entry of strains of R. trifolii or R. phaseoli.

It should be noted that the techniques used here did not enable us to determine whether the heterologous species formed bacteroids in pea nodules since only the undifferentiated bacteria can form colonies on plates. Nor was it possible to determine where the heterologous strain occurred within the nodules. Transfer of the plasmid RP4 between strains of R. leguminosarum has been observed in pea nodules[1,2], but it was not found in any of the thirteen nodules that contained both R. trifolii and the RP4-carrying strain of R leguminosarum (6099). RP4, however, is transferred by conjugation in vitro from strains of R. leguminosarum to strains 6001 and 6100 at much lower frequencies than it is to strains of R. leguminosarum (A.W.B.J., unpublished observations). The failure to find transfer in the nodules therefore need not imply that the two strains were physically separated.

It has been reported that the ability to nodulate clover can be transferred by conjugation from R. trifolii to R. phaseoli[1] and by transformation from R trifolii to R. meliloti[2]. In this study the results were not explicable by transfer of the ability to nodulate peas from R leguminosarum to strain 6001 or 6100 since single colony isolates of these strains obtained from pea nodules retained their ability to nodulate clover but did not nodulate peas.

The bases of the specificity in the recognition between legumes and Rhizobium may reside in a barrier or barriers that are breached only by bacteria of the appropriate cross-inoculation group. By definition, infective strains of R. leguminosarum overcome these barriers in peas. A general explanation for the results presented is that the hetero-

R. phaseoli strain 1233 is a rifampicin-resistant mutant of the pigment (probably melanin)-producing strain 3644 in the Rothamsted collection. R. trifolii strains 6001 (rif-r) and 6100 (rif-r str-r) were derived from strain CC37 supplied by E. A. Schwinghamer. R. leguminosarum strain 922 (his rif-r) was derived from ineffective strain 330 obtained from B. Gillberg. Strain 983 (rif-r) was derived from the ineffective Rothamsted strain 1012. All other R. leguminosarum strains were derived from our wild-type effective strain 300 (ref 6): 6099 (spc-r) carries the plasmid RP4 and is ineffective; 603 (phe) was the parent of 897 (phe trp str-r) and 7482 (phe str-r); 6009 is an ineffective mutant obtained after ultraviolet treatment of 897; 7111 and 7112 were independent ineffective mutants obtained after nitrosoguanidine mutagenesis of strain 603. Culture and inoculation methods have been described before[6]. Peas (var. Dark Skin Perfection) were inoculated with about 2×10^8 of the inoculant strains. After about 4 weeks, nodules were excised, surface sterilised and crushed in 20% glycerol. Samples (0.04 ml) of the macerates were plated on suitable selective media[6,9]. The macerates were stored frozen and those that contained the heterologous strain were diluted and plated on selective media to allow enumeration of the two strains.

logous *Rhizobium* species use the apparatus induced by *R. leguminosarum* so that there is a partial breakdown in specificity. The strains of *R. trifolii* and *R. phaseoli* used do not ordinarily induce nodules on peas but we do not know if they form infections which abort before nodule formation. *R. trifolii* was unable to fix nitrogen in pea nodules. This suggests that more than one barrier prevents *Rhizobium* of one cross-inoculation group forming an effective symbiosis with a legume of a different group. This is in accord with the findings that mutants of *R. trifolii* able to nodulate peas did not fix nitrogen in this host[1] and that some strains of *Rhizobium* isolated from clover formed ineffective nodules on peas[2].

Erucic acid, an accidental additive in bread

RAPESEED oil is a stable, viscous oil utilised extensively by the baking industry in several countries as a lubricant to prevent the dough piece sticking to the container during baking. The oil is applied either to the container or directly on to the dough surface and allows the easy removal of the bread after baking. There are, however, few data available to indicate the extent to which any rapeseed oil is absorbed into the bread during processing. The question has assumed considerable importance since Roine[1] and many subsequent workers[2-4] showed that a range of laboratory animals developed heart lesions and other biochemical abnormalities when fed diets with a substantial content of rapeseed oil. These effects have generally been attributed to erucic acid[5] (13-docosenoic acid) which is the major fatty acid constituent in normal rapeseed oils (30–50% of total fatty acids)[6]. Consequently, various countries have legislated to restrict the amount of erucic acid permitted in certain foods, although no tolerances have been set specifically for baked products. This is mainly due to the assumption that erucic acid is not a natural component of the ingredients used in bread.

We have examined 20 different types of bread obtained from retail outlets in Sydney, Australia and found that all loaves contained erucic acid in concentration which ranged from 170 to 1,070 mg of erucic acid per kg of fresh loaf, with an average concentration of 405 mg kg^{-1}. A sample of wheat flour was also analysed but no erucic acid was detected (<0.2 mg kg^{-1}), and so the erucic acid in the breads can be assumed to be derived from the rapeseed oil applied just before baking. The breads analysed included plain and fancy rolls, and standard loaves of white, brown, wholemeal, rye, kibble wheat, soy flour–wheat and starch-reduced breads. The breads were dried and ground, and a sample (20 g) was extracted with solvent to remove the lipids which were saponified and methylated[7], and analysed by flame ionisation gas chromatography using a 10% DEGS–PS on Supelcoport (80/100) glass column at 190 °C with a carrier gas flow rate of 20 ml per min of nitrogen.

Measurements were also made of the distribution of erucic acid throughout a single loaf. Table 1 shows that most of the erucic acid was present in the outer layer

Table 1 Distribution of erucic acid in a bread loaf (15 cm high)

Position in loaf	mg erucic acid per kg
Base–0.2 cm into loaf	9,550 ⎫
	⎬ 3,320*
0.2–1.0 cm	1,760 ⎭
1.0–3.0 cm	50
3.0–7.5 cm (centre of loaf)	40

*Overall value for bread from base to 1.0 cm.

although some was found in the centre of the loaf. If these gradients can be applied to all loaves, then the crust slice (1 cm thick) would contain appreciable amounts of erucic acid and range from about 0.15 to 1.0% (w/w) of the crust.

Although much information has been obtained during the past 5 yr on the effects of erucic acid on animals, negligible data are available on its toxicological effects on man, and so it has been difficult to set meaningful levels of erucic acid permissible in human diets. An acceptable daily intake of rapeseed oil has been estimated to be 30 mg per kg of body weight[8], which is equivalent to about 12 mg of erucic acid per kg. Our data show that an adult would achieve this intake if of the order of 1 kg of bread was eaten per day, although more than half the daily allowance would be supplied by two crust slices. Children, however, could receive more than their total allowable intake with only two crust slices. Thus, the use of rapeseed oil as a release agent in the baking industry leads to contamination of the product with erucic acid of a magnitude sufficient to cause concern for public health. The continued use of this substance on bread should therefore be reviewed. There are rapeseed oils readily available on the international market with low erucic acid contents ($<1\%$)[9] and these could be investigated for use in the baking industry. It is probable, however, that the viscosity of these oils would not be as desirable as that of high-erucic rapeseed oils, in which case, blending with other components would be necessary.

Suppression of adenocarcinoma by the immunological consequences of calorie restriction

EARLIER extensive studies have indicated that calorie restriction as well as protein and amino acid restriction inhibit the spontaneous development of mammary or lung adenocarcinomas, hepatomas and certain chemical carcinogen-induced tumours in rodents[1-4]. Jose and Good[5-7] and Cooper *et al.*[8] have shown that chronic moderate protein deprivation in mice and rats dramatically depresses antibody production while increasing, or permitting maintenance of, vigorous cell-mediated immune responses. The latter include abilities to resist virus infection, reject skin allografts and develop killer-cell activity

Table 1 Rate of appearance of mammary tumours (MT) and mortality in C3H female mice given diet with normal or restricted calories

against syngeneic and allogeneic tumour cells. More profound chronic protein deprivation, however, depresses both cell-mediated and humoral immunity[7,9]. Walford et al.[10,11] have shown that calorie restriction delays development of immune functions at an early age but prolongs maintenance of immunological capacity and survival in long lived, tumour-free mice. Further, Fernandes et al.[12] have shown that dramatic prolongation of life of autoimmunity-prone, short lived mice was produced by life-long calorie restriction, and that tumours did not appear in these mice. Although some of the findings clearly link moderate protein and calorie restriction to heightened cellular immunity, no definitive efforts have yet been made to compare directly the influence of dietary restriction on spontaneous tumour development and immunological functions. This report presents observations on the influence of calorie restriction on development of spontaneous mammary adeno-

the development of spontaneous mammary adenocarcinoma in the female C3H/Umc mice, and more than 50% of them lived longer than 400 d. In contrast, 71% of the control group of female C3H/Umc mice on the normal (16 calories) diet developed mammary tumours by 500 d.

In Table 2 a comparison of mitogen response studies carried out by using the technique described previously[13] is presented for the spleen cells obtained from mice on the two diets. Responsiveness of spleen cells to optimum concentrations of the T-cell lectins, phytohaemagglutinin (HA17) or concanavalin A (con A) was not only maintained on the low calorie intake but actually increased. The responses to the B-cell mitogen lipopolysaccharide (LPS) were also maintained at a level at least equivalent to that achieved by spleen cells of mice in the control group.

Table 3 summarises data comparing capacity to develop

carcinoma in mice and relates the suppression of tumour development observed to alterations in immune functions produced by calorie restriction at weaning.

Four-week-old female C3H/Umc mice were fed diets comprised of 22% casein, 33% dextrose, 33% starch, 5% corn oil, 4% salt mixture and 2% vitamin mixture, as reported previously[5,8,13]. The protein-calorie-deprived mice were fed 10 calories instead of the 16 calories eaten by the control mice, but in all other respects the diets were the same. The food was provided in conditions in which each mouse consumed its entire ration each day. The influence of this form of chronic calorie restriction on survival of C3H/Umc mice is shown in Table 1. In mice of this strain, calorie restriction did not significantly alter lifespan, even though calorie-restricted mice lived longer (3/18) than any of those in the control group. Table 1 shows that the diet low in calories completely prevented

direct haemolytic plaque-forming cells (PFC) 4 d following (intraperitoneal) immunisation with sheep red blood cells (SRBCs)[14]. After the primary stimulation, the number of direct PFCs developed in the spleens of mice on a low calorie diet was markedly depressed as compared with that of the mice in the normal calorie group. In contrast, after a secondary stimulation, the PFC formation was not significantly different in the two groups. Of interest was the finding that when the spleen cells of both groups were compared for ability to generate a secondary PFC response after injection into lethally X-irradiated (950 R) recipients[15], the sensitised cells from the calorie-deprived donors showed a greater number of PFC per million cells than was generated by spleen cells from sensitised mice which had been fed the higher calorie diet. Although several interpretations for this observation are possible, a likely explanation is that a suppressor cell population active in the

*2 µCi of ^{125}IUdR (Amersham/Searle, specific activity 106 µCi µg^{-1}, Batch No. 294BA) was injected intraperitoneally 6 h after administration (intravenously) of saline or SRBCs. Twenty hours later mice were killed, spleens weighed and isotope incorporation was determined in a Gamma Counter (Nuclear Chicago).

calorie-deprived host is not as effective as it was in the intact animal at inhibiting immune response to SRBCs after transfer to the lethally X-irradiated syngeneic recipients. The irradiated mice given sensitised spleen cells from the calorie-deprived mice showed no increase, however, in absolute number of PFCs per spleen (Table 3). This might be attributed to differences in relative proportions of different subpopulations of donor cells and their capacity to migrate or to cooperate during the immune response in the spleen of X-irradiated host animals.

The technique of Zatz and Goldstein[16], which may be one means to evaluate a population of suppressor T cells by their capacity to suppress DNA synthesis *in vivo* after injection of SRBCs, was then used to determine whether the suppressor T-cell influence is indeed excessive in the spleens of the calorie-deprived C3H/Umc mice. Table 4 shows that, by this analysis increased suppressor effect for this T-cell dependent response was also demonstrable in the calorie-deprived animals. It can be seen from Table 4 that, whereas no suppressor-cell influence was demonstrable by this technique in the spleens of 3-month-old mice fed the normal calories, those fed the low calorie diet showed very marked evidence of T-cell suppressor activity.

Our findings confirm those of several investigators[1-4] in showing that calorie restriction *per se* prevents development of mammary adenocarcinoma in highly susceptible C3H/Umc mice. They also show that moderate protein and calorie restriction permits maintenance of a vigorous functional thymic cell population, as has been found with chronic protein deprivation[5,6,8,13]. Calorie restriction apparently also decreases the PFC response to T-dependent antigen in 3-month-old mice. That such a marked deficiency of PFC response to SRBCs is not due to the changes in the functional capacity of macrophages is suggested by data from a previous study[8] which indicated that macrophage function is normal in protein–calorie deprived mice. Perhaps this issue still needs to be studied more extensively. The basis of the humoral immunodeficiency in the primary response of the calorie-deprived mice might be associated *in vivo* with an endocrine hypofunction[17] which may permit a T-cell suppressive influence in the host. This interpretation is suggested by the observation that spleen-cell response *in vitro* to both PHA, con A and LPS was not altered by calorie deprivation, and that secondary PFCs in response to SRBCs are produced quite well when the previously stimulated spleen cells of the calorie-deprived animals are transferred into lethally irradiated hosts. This postulated relationship is compatible with the recent evidence presented with "T-dependent" and "T-independent" antigens, suggesting that a T-cell population present either in adult or newborn spleens possesses the ability to recognise feedback signals, and makes a decision to suppress or enhance the immune response on the basis of the amounts and molecular form of antigen given either in a suppressive or non-suppressive environment[18,19]. More direct evidence for an active suppressor-cell population in the calorie-deprived mice, as has been revealed in young NZB mice[20], was then obtained by an assay which measures DNA synthesis in the spleen. The association of this immunological perturbation with resistance

to mammary tumours and with the marked change in hormonal functions[21] and their influence on target tissues or receptor sites of a host given a calorie-restricted diet deserves extensive study.

An interesting possibility suggested but not proved by these findings is that T-suppressor cells might suppress directly the development of mammary cancer. This is a remote possibility but it should be studied directly. Another possibility is that the calorie-deprived mice whose lymphoid system is so much perturbed might lack the ability to develop still another form of suppressor cells. This latter cell type has recently been shown to occur in animals during tumour growth, and is implicated in the inhibition of cellular immune functions[22-25]. The elimination of the development of such suppressor-cell activity and/or absence of serum-blocking factors[5,6] by calorie restriction might facilitate the destruction of newly arising tumour cells by immunocompetent T lymphocytes and macrophages. The nature and mode of such immunological alterations in relationship to dietary restriction remain unknown, and further studies are urgently required to elucidate the role of nutritional manipulations in susceptibility and resistance to tumour development *in vivo*. Similarly, although these studies and previous investigations from our laboratories seem to suggest that immunity could be involved in the resistance to tumours produced by low calorie diet, much further study will be needed to elucidate these relationships.

Mechanisms of bone destruction in the development of skeletal metastases

SKELETAL metastases are associated with progressive bone destruction but the pathogenesis is not well understood. I report here experiments which indicate that two principal mechanisms are involved. The first is mediated by osteoclasts and the tumour secretes a diffusable osteoclast activating factor; the second functions when the residual trabeculae are surrounded by the tumour cells.

Several hundred specimens of bone, obtained at autopsy from the spines of 68 patients who died from various malignant diseases[1], were fixed in neutral formalin and decalcified in 5% nitric acid until no residual calcification was seen radiographically. Sections were then stained with haematoxylin and eosin and examined microscopically.

A suspension of VX2 carcinoma was obtained by finely dividing approximately 1 g of tumour in 5 ml of 0.15 M NaCl, producing approximately 2.5×10^8 cells per ml. In the first group a 0.5-ml sample of the suspension was injected into one tibia or ilium of New Zealand white rabbits or on to the periosteal surface. With tibial implants (16 rabbits), the bone was exposed at operation under ether anaesthesia, and a fine drill hole, just large enough to accommodate a size 18 needle, was made through one cortex. The tumour cell suspension was injected well down the medullary cavity using a bent size 18 needle. In the first few experiments the hole was plugged with bonewax, but this was found to be unnecessary and was discontinued. Iliac implantation was made by percutaneous injection into the iliac crest (six rabbits) or into a hole drilled in the ilium at open operation (six animals); all the periosteal injections were percutaneous (12 rabbits).

In half the animals 0.15 M NaCl was injected into the contralateral bone; in the others no operation was performed on this bone. The rabbits were killed at intervals from 24 h to 8 weeks later, and specimens from both the injected and the contralateral bone were treated in the same way as the human necropsy specimens. In the second group of 33 rabbits, 1 ml of tumour cell suspension was used by the other experimental details were the same.

Fig. 1 Metastasis from prostatic carcinoma. There is considerable new bone formation (B) in the stroma of the tumour. Multiple osteoclasts (arrowed) can be seen, adjacent to areas of bone destruction ($\times 96$).
Fig. 2 Section taken 24 h after the injection of VX2 carcinoma. Osteoclasts are prominent (arrowed) near the tumour mass (T), and each is associated with localised bone destruction. Osteoblastic proliferation with new bone formation is also present (B) ($\times 120$).

In the third group (four rabbits) the tumour cell suspension was placed in a diffusion chamber with a 0.45-μm Millipore filter, which was then implanted near the ilium but separated from it by normal muscle. In two of these rabbits a diffusion chamber containing saline was inserted on the contralateral side; the other two had no contralateral operation. The rabbits were killed 8 d later and sections from the left and right pelvis were treated as described previously.

In the fourth group, 4 ml of tumour cell suspension was injected percutaneously into the thigh muscle close to one femur, and the animals were killed 45–55 d later. Sections obtained from the distal and proximal tibiae and the femora were treated as described before. In addition, counts were made of the osteoclasts in each cross section, using a magnification of 200. At least two sections from each site were examined.

Study of the post-mortem sections suggested that there were two distinct mechanisms for the bone destruction. In many instances the bone surface was lined by numerous osteoclasts with local resorption occurring in the lacunae around each osteoclast (Fig. 1). In other sections the bone edge had a trabeculated appearance, suggesting that this was due to osteoclastic lacunae, although no osteoclasts were seen in the lacunae. This occurred with all types of tumour. Osteoclastic proliferation and bone destruction were independent of the associated osteoblastic reaction and new bone production[1]. The osteoclasts were not part of the tumour mass, and usually fibrous reactive stroma filled the space between the edge of the tumour mass and the osteoclasts. Osteoclasts were seen when the associated bone destruction was not gross, but when there were only residual spicules of bone surrounded by tumour cells, osteoclasts were absent.

The first change seen in the rabbits (at 24 h) was osteoclastic proliferation separated from the tumour by a small amount of fibrous stroma (Fig. 2). Surrounding each osteoclast was a small lacuna with bone destruction. Some osteoblastic reaction with new bone formation was also seen at this stage. As the tumour grew, osteoclasts proliferated. As the tumour edge approached the endosteal surface of the cortex, localised destruction occurred in which osteoclasts were prominent. Once the tumour mass actually reached the endosteal surface of the residual cortex, osteoclasts were seen in large lacunae within the cortex. At this stage, there was periosteal new bone formation, associated with the osteoclastic proliferation and cortical bone destruction. When the tumour was injected on to the periosteal surface osteoclastic destruction of the

Fig. 3 Metastasis. Residual trabecula of bone (B) surrounded by tumour (T). Osteoclasts are absent (×96).

cortex, extending from the periosteum to the endosteal surface occurred, the osteoclasts always preceding the tumour.

The osteoclasts disappeared once the tumour had grown sufficiently large to envelop a residual trabecula of bone, but bone destruction continued (Fig. 3). In a few animals osteocytic osteolysis occurred in the tibial cortex, but this accounted for only a minute amount of the bone loss. Occasional infarcts were seen. They usually included bone as well as tumour, and were responsible for only a small amount of the total bone destruction.

Tumour cells implanted in the diffusion chamber remained there as shown by subsequent histological examination, as did the normal muscle between the chamber and the ilium. Osteoclastic proliferation was seen on the periosteal surface and even in the medullary cavity. There was no osteoclastic proliferation on the contralateral side.

Tremendous osteoclastic proliferation occurred in the femur when tumour cells were injected into an adjacent muscle. Their number diminished progressively as the distance from the tumour increased. There was no

Fig. 4 VX2 cell suspension injected into the left thigh, and the number of osteoclasts per cross section of bone counted at various sites. The number progressively diminishes the more distal the section from the tumour. There is no osteoclastic proliferation on the contralateral side.

Number of osteoclasts

osteoclastic proliferation on the contralateral side (Fig. 4).

These experiments suggest that destruction of bone associated with metastatic invasion involves at least two mechanisms, and possibly others of less importance. The initial mechanism, apparently the more important quantitatively, was mediated by osteoclasts. The diffusion chamber experiments suggest that the tumour secreted a humoral factor which stimulated osteoclastic proliferation locally but not on the contralateral side. This was confirmed by the experiments with large amounts of tumour cell suspension implanted in the thigh muscle; the number of osteoclasts progressively decreased distally. Since the contralateral side was unaffected, the results indicate that if this substance enters the circulation, it is rapidly inactivated. Further experiments suggest that prostaglandins are involved[2].

The tumour cells seem to mediate late bone destruction by a mechanism not involving osteoclasts. Osteocytic osteolysis seems of little importance; it was found in the tibial cortex in only a few rabbits and caused only a minute amount of total bone destruction. It was not seen in the human necropsy material. Tumour proliferation may be associated with thrombosis of the vessels and ischaemia, but this was not a feature in the experimental animal or in the necropsy material.

Previous studies have shown that skeletal metastases are associated with both new bone formation and destruction, which occur simultaneously[1]. There seem to be at least two mechanisms for the bone formation. When the tumour provides a suitable matrix for ossification, bone is laid down if osteoprogenator cells are available, for example, metastases from prostatic carcinoma. New bone is formed in all metastases once there is some bone destruction. This is similiar to callus repair after a fracture and may be due to stress on the weakened bone[1]. The present studies suggest that this occurs during osteoclast-mediated bone destruction. Once the destruction was gross and malignant cells surrounded the residual bone, no new bone was formed and no osteoclasts were seen. This may explain the occasional false negatives in skeletal scintigrams when X-rays demonstrate large lytic metastases—at this stage there is no reactive new bone to concentrate the bone-seeking isotope.

Relationship of bone destruction in skeletal metastases to osteoclast activation and prostaglandins

Two principal mechanisms seem to be responsible for the bone destruction associated with skeletal metastases. The earlier and quantitatively most important mechanism seems to be mediated by osteoclasts stimulated by material produced by the tumour[1]. We now report evidence that this material is, or contains, prostaglandin. There are precedents for such a conclusion. Various tumours contain prostaglandins[2], which resorb bone in organ culture[3]. Prosta-
Fig. 1 The effect of indomethacin on osteoclast proliferation near the VX2 carcinoma. There is a marked reduction in the number of osteoclasts (per 100 possible sites) in the tumour-bearing tibiae but no change in the control tibiae. a, Control; b, treated with indomethacin.

glandin formation may explain the growth of dental cysts in the human jaw[4], and prostaglandin synthetase inhibitors reduce tumour-induced osteolysis[5] and hypercalcaemia[6].

The experimental model used is good for investigating skeletal metastases. Approximately 1 g (fresh weight) of VX2 tumour, grown in the thigh muscles of donor New Zealand white rabbits, was finely divided by scissors in 5 ml of 0.15 M sterile NaCl, producing a suspension containing approximately 2.5×10^8 cells per ml. In 16 New Zealand white rabbits 1 ml of cell suspension was injected into the thigh muscle. Eight animals were given indomethacin 7.5 mg per kg body weight per d in their drinking water, starting at intervals varying from 7 d before tumour implantation to immediately after implantation.

The other eight animals, paired with animals receiving indomethacin, served as controls. Each pair received tumour cells from the same donor and was killed simultaneously. Tumours were examined for prostaglandins by homogenising weighed amounts in either Krebs' solution (to indicate synthesising ability) or in 50% ethanol acidified to approximately pH 3 with formic acid (to indicate "basal" levels)[8]. The prostaglandin-like material was extracted and assayed on the rat fundus strip preparation against prostaglandin E_2 (PGE_2)[9]. Part of the extracted Krebs' solution homogenate was characterised by AII solvent system chromatography using paper impregnated with silica gel[10] followed by bioassay.

In 16 other rabbits 1 ml of tumour cell suspension was

Fig. 2 X rays of tibiae removed 31 d after injection of VX2 tumour cell suspension. The tibia on the left is from the control animal, that on the right from the indomethacin-treated animal. There is a marked reduction in the amount of bone destruction in the indomethacin-treated animal.
injected into the proximal tibia through a fine drill hole which exactly fitted a bent 18-gauge needle. Half the animals were treated with indomethacin (7.5 mg per kg body weight per d in the drinking water starting 1–7 d before tumour implantation). Indomethacin-treated animals were paired with controls which received tumour from the same donor. Radiographs of the tibiae were taken at intervals and when each pair was killed simultaneously 4–45 d later. Both tibiae were removed, fixed in formalin, decalcified in 5% nitric acid and embedded in wax. At least three histological sections, 1 mm apart, were cut from the proximal part of each tibia, and stained with haematoxylin and eosin. The osteoclasts were counted in each section using a cross-hatched eyepiece graticule and a magnification of 200: an osteoclast was counted if it lay under one of the cross hatches, but not if it lay between two cross hatches. Six hundred randomly selected sites were examined in each section and the number of osteoclasts per 100 sites was calculated.

The animals drank the indomethacin-treated water and the dose of indomethacin required was achieved. In both experimental groups, the lungs at autopsy were filled through the trachea with 15% Indian ink in distilled water containing 1 ml of ammonia per l of solution, removed and fixed in acetic acid–ethanol–formalin–distilled water (2 : 28 : 4 : 66 v/v). The pulmonary metastases, appearing as white areas on a black background, were counted on the external surface and in 1-mm slices through each lobe. The statistical tests included the paired t test.

High concentrations of prostaglandin-like material were extracted from the tumours from animals not receiving indomethacin (Krebs' solution homogenates 4.73 ± 1.06 (s.e.)μg PGE_2 equivalents per g; acid ethanol homogenates 2.4 ± 0.63 μg). The difference between these results is statistically significant ($P < 0.01$). Tumours from indomethacin-treated animals contained significantly less prostaglandin-like material (0.19 ± 0.07 and 0.24 ± 0.15 μg PGE_2 equivalents, Krebs' solution and acid ethanol homogenates respectively, both significantly less than controls, $P < 0.01$). Paper chromatography of extracted Krebs' solution and acid ethanol homogenates (nine and seven tumours, respectively) indicated that all the material was PGE_2. The activity ran fractionally slower than authentic PGE_2, but pure PGE_2 added to the extracts (three experiments) was slowed to the same extent presumably due to extracted impurities.

The number of osteoclasts in the tumour-bearing bone was significantly less in the indomethacin-treated animals (5.2 ± 1.71 osteoclasts per hundred sites) compared with controls (11.1 ± 2.13; $P < 0.05$) (Fig. 1). The numbers were low in the contralateral tumour-free tibiae of indomethacin-treated (0.6 ± 0.09 osteoclasts) and control animals (0.5 ± 0.22 osteoclasts). X rays revealed that in the indomethacin-treated animals bone destruction was markedly diminished but not prevented (Figs 2 and 3).

The number of pulmonary metastases tended to be higher (253 ± 67) in the indomethacin-treated animals than in the controls (189 ± 40), but the difference was not statistically significant ($P > 0.4$).

There is substantial evidence that secretion of prostaglandin by the tumour cells contributes to the activation of osteoclastic bone destruction. The tumour seems to be able to synthesise substantial amounts of PGE_2 as judged by chromatography and bioassay. This supports the conclusion of Voelkel et al. based on radioimmunoassay, the only difference being the amount of PGE_2-like material present. We found 4.73 ± 1.06 μg PGE_2 equivalents per g fresh tissue in our Krebs' solution homogenates. This represents the "basal" amount present plus prostaglandin newly synthesised during homogenisation, less any inactivated. Our "basal" levels are indicated by the acid ethanol homogenates where enzyme activity is inhibited.

Fig. 3 X rays of tibiae removed 45 d after injection of the VX2 cells. The tibia on the left is from the control animal, that on the right from the indomethacin-treated animal. There is a marked reduction in the amount of bone destruction in the latter.

The "basal" values of 2.4 ± 0.63 µg PGE_2 per g are surprisingly high compared with other tissues (for example, human breast[11,12]). Voelkel *et al.* call their level of 0.294 ± 0.051 µg PGE_2 per g fresh weight "content", but since this was obtained after homogenising in a balanced salt solution, it presumably includes newly synthesised material and should be compared with aqueous homogenates. Apart from biological variation, their approximately 16 times lower levels might be due to losses during preparation and extraction (recoveries not stated); differences in time after implantation are unlikely to be important. Our studies confirm the findings of Voelkel *et al.* that feeding indomethacin to the rabbits greatly reduces the amount of extractable tumour prostaglandin. Although they looked at hypercalcaemia whereas we looked at bone destruction, both sets of data strengthen each other.

The reduction of the number of osteoclasts by indomethacin can be explained by the blockade of prostaglandin synthesis which this drug produces[13]. The failure to eliminate all production of osteoclasts and bone destruction might be due either to incomplete inhibition of prostaglandin synthesis, or to the involvement of other osteoclast-activating material (for example, a parathormone-like principle[14]). Furthermore, it is clear that bone destruction can occur without osteoclast involvement in late stages when the tumour cells surround the bone. It therefore seems likely that indomethacin or similar drugs would inhibit both the formation of human bone metastases, and their growth in the early stages. This supports the trial undertaken with benorylate in breast cancer patients with no evidence of bone metastases (personal communication from T. J. Powles), particularly as the synthesis of prostaglandin-like material by human breast tumours may be involved in the development of bone metastases[11,12]. Indomethacin has been used in the treatment of hypercalcaemia due to malignant disease[15] but was not successful in advanced mammary cancer (T. J. Powles, personal communication). These metastases have not been examined histologically, but their radiological findings are consistent with stage II disease[1].

In rats with Walker tumour, aspirin and indomethacin inhibited the hypercalcaemia and osteolysis, demonstrated radiographically, but not examined histologically[5]. There was no significant difference in the soft tissue deposits; the tendency for more pulmonary metastases in our experiments was not statistically significant, and indomethacin treatment did not alter longevity (unpublished data). These results do not support the suggestion[16] that PGE_2 is immunosuppressive and that indomethacin might retard tumour

growth. The formation of soft tissue metastases during treatment with indomethacin may have implications for treatment of bone metastases in human subjects, although it may not be appropriate to compare the effects of a massive injection of tumour cells into rabbits with a slower shedding of cells from human primary tumours. Presumably cells shed slowly from the primary tumour in the presence of indomethacin would not readily develop into skeletal metastases, but it remains to be seen whether they develop elsewhere. Chemotherapy would seem necessary to eradicate the tumour cells, and it might be desirable to treat the patients simultaneously with inhibitors of prostaglandin synthesis.

Decreased renal prostaglandin catabolism precedes onset of hypertension in the developing spontaneously hypertensive rat

WE have shown in kidneys from normotensive rats, that dramatic age-related changes take place in the catabolism, but not in the biosynthesis, of prostaglandins (PGs)[1]. Although PG catabolic enzymes were active in the late prenatal period, they rose to a peak (60-fold relative to the adult) around 19 d postnatally, dropping to adult levels by day 40 (ref. 1). We have termed this period of peak activity of PG catabolism the 'critical prostaglandin period'[2]. Since the PG catabolising system is principally located in the cortex[3,4], and since cortical maturation is almost entirely a postnatal event (during the first 4–5 weeks) supported by an intrarenal blood flow redistribution[5], the sharp increase in PG catabolism implied an intrinsic requirement by the developing kidney to eliminate locally-formed or plasma PGs. PG catabolism possibly functioned as a protective measure[1] against the potentially harmful effects of the PGs which in this species possess potent vasoconstrictor properties[6]. We theorised that unless inactivated, these compounds could interfere with the redistribution of blood flow to the cortex and consequently with normal corticogenesis. We were therefore interested in investigating the activity of the PG

system in spontaneously hypertensive rats (SHR) at various stages of pre- and early hypertension to compare this activity with age-paired groups of control normotensive rats in an attempt to determine first whether an abnormality in the prostaglandin system exists, second, whether this abnormality appears around the 'critical prostaglandin period' and, third, whether this abnormality develops before or after the onset of hypertension.

Litters (4–7 d) of male SHRs of the Wistar Okamoto–Aoki strain and age-paired normotensive (NR) controls of the Wistar–Kyoto strain were purchased from Laboratory Supplies (Indianapolis) and housed in our animal quarters. Free access to food and water was provided. At various ages one rat from three SHR and three NR litters was killed. The kidneys from each group were combined and homogenised in twenty volumes of buffer (0.05 M KH_2PO_4–$NaOH$, pH 7.4).

PG catabolism was assayed by the radioisotope-dilution method reported previously[1]. Briefly, 0.5 ml homogenate (corresponding to 50 mg wet tissue, approximately 6.5 mg protein) was added to test tubes containing 5,6-$^3H_2$-PGF$_{1\alpha}$ (500,000 d.p.m., New England Nuclear, specific activity 89 Ci mmol^{-1}) containing 0, 1, 5, 10, 30 and 50 μg unlabelled PGF$_{1\alpha}$ and NAD (4 mM final concentration) and tubes were incubated for 10 min at 30 °C. Ethanol (2.5 ml) was added to terminate the incubation and after centrifugation, the supernatant was transferred and evaporated to dryness *in vacuo*. Each sample was assayed qualitatively by radio thin-layer chromatography using chloroform–methanol–acetic acid–water (90:9:1:0.65 v/v) as developing solvent (R_f PGF$_{2\alpha}$ = 0.13; 15K-PGF$_{2\alpha}$ = 0.25, 15K-H$_2$-PGF$_{2\alpha}$ = 0.36) and each product subsequently quantitated by scintillation counting as reported previously[1]. Protein in homogenates was measured by the method of Lowry[9].

PG biosynthetic capacity was measured by mass fragmentography using the stable-isotope dilution technique[7]. An aliquot (10 ml, corresponding to 0.5 g wet tissue, approximately 65 mg protein) of the same homogenate was incubated with excess arachidonic acid (100 μg g^{-1}) 10 min, 37 °C in an oxygen atmosphere. The incubation mixture was acidified to pH 3 with 0.5 N HCl and diethyl ether was added (10 volumes). A mixture of 3,3,4,4-tetradeuterated PGE$_2$, PGF$_{2\alpha}$ and 15-keto-13,14-dihydro-PGF$_{2\alpha}$ (1 μg each) was added followed by a mixture of high specific activity 5,6-tritiated PGE$_1$, PGF$_{1\alpha}$ and 15-keto-13,14-dihydro-PGF$_{1\alpha}$ (500,000 d.p.m. each, approximately 0.7 ng). After extraction, conversion to methyl esters and purification by thin-layer chromatography (R_f PGF$_{2\alpha}$Me = 0.28; PGE$_2$Me = 0.40; 15K-H$_2$-PGF$_{2\alpha}$Me = 0.48), each compound was quantitated as described previously[8].

Table 1 shows the PG biosynthetic and catabolising capacity of

Table 1 Renal biosynthesis and catabolism of PGs by the normotensive (NR) and spontaneously hypertensive (SHR) male rat at various ages

Age		15-PGDH ng per min per mg protein	PGE$_2$ + PGF$_{2\alpha}$ ng per g tissue per 10 min
4 d	NR	76.5	
	SHR	100.1	
17 d	NR	221.6	380
	SHR	124.2	460
49 d	NR	8.9	1,620
	SHR	6.9	2,120
Adult	NR	7.6;6.5	1,520
	SHR	2.9;2.7	2,440

homogenates of kidneys from SHR and NR rats at four different ages. As observed previously[1] 15-PGDH catabolising activity varies immensely with age (about 60-fold around 3 weeks with respect to the adult) whereas the biosynthetic activity does not. Although the combined levels of PGE$_2$ and PGF$_{2\alpha}$ at 17 d are approximately 20–30% of the adult, this difference can be largely explained by the high catabolising activity at 17 d. On the other hand, by comparing the relative capacities of 15-PGDH and the biosynthetic systems between NR and SHR rats it is evident that after 17 d of age the SHR rats possess lower renal catabolic activity. This is also supported by the apparent higher biosynthetic activity of SHR rats (Table 1).

The progressive difference between renal 15-PGDH activity in SHR and NR rats can best be seen in Fig. 1. Renal 15-PGDH activity in male adult SHR is approximately 40% of that found in NR. Before 1 week of age, SHR renal 15-PGDH activity is greater than NR decreasing to adult levels shortly after by 3–6 weeks. On the other hand, although no blood pressure differences are observed between the two types of rats at 3 weeks of age, differences become evident around 7 weeks of age. It is interesting that around this time a spurt in 15-PGDH activity occurs but this quickly returns to adult levels by 10 weeks of age.

The pattern of decreased 15-PGDH activity with age might not be typical of all types of hypertension. Armstrong *et al.*[10] reported similar observations as ours with adult genetic hypertensive rats (GH) of the New Zealand strain but they failed to observe any differences with the Japanese spontaneous hypertensive rat. Unfortunately these authors did not carry out ontogenetic studies with either one of these strains, nor did they provide an indication of the types of PGs formed by these rats.

Our experiments demonstrate that (1) an abnormality in renal PG catabolism (Fig. 1) is evident in SH rats of the Wistar Okamoto–Aoki strain. (2) This abnormality develops in the pre-hypertensive stage reaching the adult level before the appearance of an elevation in blood pressure (3) higher PG biosynthetic capacity is observed in adult SHR than NR, but this reflects the lesser 15-PGDH activity. Thus it is possible that the hypertension that develops around 5–7 weeks of age in SH rats is due to renal 'damage' resulting from the inability to degrade effectively PGs especially during the 'critical prostaglandin period'.

Transformation of thymocytes by thymus epithelium derived from AKR mice

TYPE C RNA viruses result in the appearance of lymphomas and leukaemias when injected into genetically susceptible strains of mice[1]. The relationship between the murine leukaemia viruses (MuLV) and their target cells in the induction of leukaemia remains, however, incompletely defined. Although MuLV viruses are ubiquitous in the tissues of many mouse strains and are present throughout the life of the animal, they transform specific haemopoietic cell types into leukaemic cells only after a relatively long latent period[2–5]. This suggests that leukaemia is not caused by the virus alone but that a special interaction exists between viruses and target cells in a particular stage of differentiation and maturation.

The target cells of thymotropic MuLV such as radiation leukaemia virus and Gross virus seem to be thymocytes and/or prothymocytes, since the transformed cells have many T-lymphocyte characteristics and they first appear as neoplastic foci in the thymus[6–8]. That differentiation events are important in leukaemogenesis is suggested by changes in the mitogen responsiveness of thymocytes during the latent period before the onset of disease and by change in the relative amounts of cell surface Thy 1 and H–2 antigens in both the spontaneous AKR- and radiation-induced C57BL mouse leukaemia models[9–11]. In both of these systems the incidence of leukaemia is dramatically reduced after thymectomy, which demonstrates the central role played by the thymus[12,13]. The thymic microenvironment may therefore be involved directly or indirectly, through factors released by the epithelium, in the induction of leukaemia by MuLV.

In earlier studies we have used cultures of pure thymus epithelial cells (TE) to simulate the thymic microenvironment *in vitro* to study the induction of differentiation of precursor cells into mature T lymphocytes[14,15]. In the studies reported here, we used TE cultures to investigate the contribution of the thymic microenvironment to leukaemogenesis *in vitro*.

To analyse the role of target cell differentiation as a cofactor in leukaemogenesis we have used lymphoctyes naturally in-

Table 1 Survival of AKR/J mice receiving syngeneic 6-week-old AKR/J thymocytes cultured on thymus epithelium from aged mice

Inducing monolayers	Survival of 6-week old AKR/J recipients†
MEF (AKR/J)*	264 ± 63 d
Kidney epithelium (KE) (4 weeks)	251 ± 69 d
KE (> 24 weeks)	243 ± 74 d
Thymus epithelium (TE)	256 ± 70 d
TE (> 24 weeks)	46.8 ± 6.9 (31–61)

*Mouse embryonic fibroblasts.
†Survivals are reported as the mean ± s.d.
Thymocytes obtained from 6-week-old female AKR/J were cultured together with the inducing cell monolayers in 60 mm Falcon culture dishes (30×10^6 thymocytes per 60-mm dish) containing RPMI 1640 + 15% FCS + 2-mercaptoethanol. After 48 h of culture the monolayers were washed by gentle pipetting with Hanks' balanced salt solution (HBSS). The thymocytes were washed in HBSS and resuspended in phosphate-buffered saline. Thymocytes from each group of inducing monolayers were injected intravenously into 8-week-old syngeneic recipients. 2×10^6 thymocytes were transferred into each animal and each group consisted of 30 mice. The groups were then studied for survival. Only the group receiving cells cultured on TE cells derived from AKR mice over 24 weeks old died after a short latent period with a mean survival of 46.8 ± 6.9 d. The range was between 31 and 61 d. The animals in the control groups did not begin dying of leukaemia until after 150 d.

fected with MuLV as targets for differentiation signals produced by TE. The AKR mouse provides a suitable model since MuLV (Gross type) has been detected in all cell types tested in this strain from before birth[16]. AKR mice develop leukaemia with 90% incidence only after they are 24 weeks old[17]. The AKR model would therefore allow us to study the role of differentiation and maturation of target lymphocytes while avoiding the need to add exogenous MuLV.

The experimental design was to culture TE cells from young non-leukaemic and aged AKR/J mice and to test the ability of these TE cells to transform naturally infected young AKR lymphocytes into neoplastic cells *in vitro*. The technique of TE cell culture has been published in full elsewhere[18]. Briefly, thymuses were removed asceptically, minced, and treated with trypsin–EDTA solution (GIBCO) and collagenase (Worthington Biochem). The cells were grown in monolayer culture in Dulbecco's modified Eagle's medium containing 15% foetal calf serum (FCS). Control monolayers consisted of kidney cells, from young and aged mice, as well as embryonic fibroblasts.

Thymocytes obtained from 6–8-week-old AKR/J mice were cultured together with supporting cell monolayers listed in Table 1 for 48 h. The thymocytes were collected from the culture dishes by gentle pipetting of the monolayer surface with Hanks' balanced salt solution (HBSS). In this way the monolayers are not disrupted and supporting cells are therefore not transferred along with the thymocytes. To ensure this, the culture dishes were each examined microscopically after the thymocytes were removed. The thymocytes were then washed in HBSS and resuspended in phosphate-buffered saline for injection into 8-week-old syngeneic recipients. Thymocytes cultured on TE monolayers from aged (more than 24 weeks old) AKR mice and then transferred into syngeneic recipients killed these animals after a short latent period. The animals died of lymphoma and leukaemia between 31 and 61 d after injection, as evidenced by splenomegaly, lymphadenopathy, and leukaemic nodules in the liver at post-mortem pathology. TE of aged AKR mice were effective in inducing leukaemia whether or not they were derived from the thymuses of overtly leukaemic mice. In contrast, thymocytes cultured on TE obtained from 4-week-old AKR mice did not kill the syngeneic recipients, and these animals died of spontaneous leukaemia only after 24 weeks of age as did uninjected control AKR mice. Also, as shown in Table 1, cultures of embryonic AKR fibroblasts or kidney epithelium from young or old, overtly leukaemic mice were unable to shorten the latent period.

These results indicated that the injection of the donor thymocytes led to the appearance of leukaemia in young syngeneic recipients. It was possible, however, that the leukaemia itself originated in the recipient mice and the leukaemogenic process was only hastened by the injection of the donor thymocytes. It was therefore necessary to ascertain whether true leukaemogenesis of the donor thymocytes had been induced *in vitro*.

We used AKR thymocytes with different alleles of the Thy 1 genetic marker to establish whether the recipient animals died of leukaemia or donor or host cell origin. AKR/J thymocytes, bearing the surface antigen Thy 1.1, that had been cultured on TE cells were injected into 8-week-old AKR/Cu mice whose T lymphocytes bear the Thy 1.2 alloantigen. In every AKR/Cu mouse studied the majority of the leukaemic cells in their spleens were positive for Thy 1.1, showing the disease to be of donor rather than host cell origin (Table 2). When AKR/Cu (Thy 1.2) thymocytes were cultured on TE for 48 h and injected into AKR/J (Thy 1.1) mice, the spleens of the recipients contained Thy 1.2 positive leukaemic cells (Table 2).

The genetic origin of the TE cells whether from AKR/J (Thy 1.1) or AKR/Cu (Thy 1.2) did not determine the *Thy 1* alleles of the leukaemic cells (Table 2). This argues against the possibility that the leukaemia was derived from the old TE cells themselves or from thymocytes that could have originated from the old AKR mice from which the TE cells were obtained. We concluded therefore that the leukaemia cells developing

Table 2 Donor origin of transformed leukaemic cells *in vitro*

| Donor thymocytes | | Inducing TE cells from | | Thy 1 type on leukaemic spleen cells | | |
Strain	Thy 1 Allele	24+-week-old AKR mice Strain	Allele	Recipient	% Thy 1 ±s.e. Thy 1.1	Thy 1.2
AKR/J	Thy 1.1	AKR/J	Thy 1.1	AKR/Cu	83±1.2	8±0.5
AKR/J	Thy 1.1	AKR/Cu	Thy 1.2	AKR/Cu	80±0.9	6±0.5
AKR/J	Thy 1.1	AKR/J	Thy 1.1	AKR/J	71±1.6	5±0.9
AKR/Cu	Thy 1.2	AKR/J	Thy 1.1	AKR/J	9±0.8	79±1.7
AKR/Cu	Thy 1.2	AKR/J	Thy 1.2	AKR/Cu	<3	87±1.4
AKR/Cu	Thy 1.2	AKR/Cu	Thy 1.2	AKR/Cu	<3	78±1.7

Thymocytes obtained from 6-week-old female AKR/J or AKR/Cu mice were cultured together with thymus epithelium from AKR/J or AKR/Cu mice more than 24 weeks old in RPMI 1640+15% foetal calf serum+2-mercaptoethanol. Thymocytes were collected by gently pipetting the monolayers with Hanks' balanced salt solution. The thymocytes were resuspended in phosphate-buffered saline and 5×10⁶ cells were transferred to 8-week-old AKR/J or AKR/Cu mice by intravenous injection. Each group contained 30 animals. Fifteen animals were killed after 30 d and cytotoxicity experiments were performed on individual spleens with anti-Thy 1.1 and anti-Thy 1.2 sera. Single-cell suspensions were prepared and the cell concentration was adjusted to 5×10⁶ viable cells ml⁻¹ with a final concentration of antisera at 1:8. Guinea pig complement was added after 30 min at a concentration of 1:4. Percentage viable cells was determined by Trypan blue exclusion. The results are reported as the means±s.e. of the maximum cytotoxicity of individual spleens.

Also 15 animals from each group were studied for survival. 100% of the mice in each group died after a short latent period. The results show that in each group the leukaemic cells were of donor rather than host origin

in the recipient mice originated from the donor thymocytes which had been incubated with the TE cells. Thus, the TE cells induced leukaemic transformation of young thymocytes naturally infected with MuLV.

Did the cultured thymocytes actually become leukaemic during the *in vitro* culture period? Did the TE cells provide a signal in itself sufficient for leukaemic transformation, or did they merely initiate a process that required further differentiation stimulated *in vivo* by the thymuses of the recipient mice?

To study these questions we performed thymectomy of recipient mice and injected them with donor thymocytes which had been cultured on TE cells. As shown in Table 3, we found that the donor thymocytes could manifest leukaemia even in thymectomised recipients. This finding suggests that the induction of leukaemia was initiated by contact with TE cells cultured *in vitro* and that continued contact with a thymus *in vivo* was unnecessary for leukaemic transformation. Thus 48 h or less of contact with TE cells *in vitro* was sufficient for triggering of leukaemogenesis.

In the present study thymus epithelium from aged AKR/J mice has been shown to initiate directly leukaemic transformation of thymocytes *in vitro*, in the absence of any added MuLV. When TE cells are injected into mice either subcutaneously or under the kidney capsule no tumour is formed. Injection of TE cells does, however, induce leukaemia in the recipient animals. Here the transformed cells are of host rather than donor origin. Mice receiving TE cells from old AKR mice die of lymphoma and leukaemia between 3 and 5 weeks (S. D. Waksal, in preparation).

What is the mechanism of this leukaemogenesis? Other tissues of aged AKR mice such as kidney epithelial cells contain replicating MuLV particles and yet were unable to transform thymocytes *in vitro*. In fact the target lymphocytes themselves already contain similar MuLV. Therefore, leukaemogenesis must involve more than the mere transfer of such viruses.

It has been shown that the thymus has an important role in this disease, since thymectomy up to 5 months of age can markedly inhibit the incidence of the disease in AKR mice[18]. The thymus is responsible for the differentiation and maturation of thymocytes and thymus-derived lymphocytes. The target cell for both normal thymic activity and leukaemogenic transformation seems to be the prothymocyte or thymocyte[8,19,20]. Thus the target cells of the leukaemogenic process might have to be in a critical stage of differentiation to be susceptible to the transforming potential of the MuLV with which they are already infected. The TE cells could activate leukaemia by inducing this necessary stage of differentiation. In support of this concept is our finding that mature lymph node lymphocytes cannot be transformed into leukaemic cells by old TE *in vitro* (S. D. Waksal, unpublished results). Such lymphocytes which have

already passed through the thymic microenvironment are also refractory to further differentiation caused by the TE cells *in vitro* (S. D. Waksal et al., in preparation).

Leukaemic transformation of lymphocytes or their precursors has also been achieved *in vitro* using Abelson virus[21,22]. Here too the state of target cell differentiation seems to be important since the target cells used for transformation are either lipopolysaccharide-stimulated spleen cells or foetal liver cells. The former population contains B lymphocytes non-specifically triggered to differentiate and the latter a population of cells which contain precursors differentiating into B lymphocytes.

It is, however, unlikely that a normal differentiation signal is the sole contribution to leukaemogenesis of the TE cells in our system. TE cells obtained from young AKR mice are capable of inducing the normal differentiation of thymocytes into T lymphocytes but do not provide the leukaemogenic signal (Table 1). Other factors must, therefore, distinguish old from young thymus epithelium. Such factors might include mechanisms which allow the endogenous MuLV to become leukaemogenic within the thymic microenvironment. There may also be a requirement for a second helper virus or viruses which replicate in the TE cells to produce leukaemogenesis in combination with the Gross-type MuLV. TE cells from aged AKR mice have significantly higher levels of replicating MuLV than TE cells from young mice. This has been observed using

Table 3 Effect of thymectomy on survival of AKR mice receiving syngeneic 6-week-old AKR/J thymocytes transformed by TE cells *in vitro**

Inducing monolayer (AKR/J)	Survival ATx recipient†
Kidney epithelium (4 weeks)	> 285 d
Kidney epithelium (>24 weeks)	> 330 d
TE (4 weeks)	> 330 d
TE (> 24 weeks)	44±6.9 d (32–53)

*Thymocytes from 6-week-old female AKR/J mice were cultured together with the inducing monolayers for 48 h. The thymocytes were collected by gentle pipetting of the monolayer surfaces and 5×10⁶ cells were transferred into groups containing 25 syngeneic 8-week-old recipients. Each recipient had been thymectomised at 4 weeks of age. Only 1 out of 25 mice which had been adult thymectomised but received no transferred cells developed lymphoma with latent period of 187 days. AKR/J mice which had been thymectomised and received thymocytes cultured together with TE monolayers from AKR/J mice over 24 weeks old died of lymphoma after a short latent period (44±6.9 d) with splenomegaly and lymphadenopathy. Only 2 animals in the control adult thymectomised groups died of leukaemia. The other control mice were still alive beyond days listed in Table 3.

†Survival of the last group is reported as the mean survival±s d. with a range of 32–53 d.

fluorescent anti-MuLV. These higher levels of virus may be critical in the development of leukaemia. These viruses might include the AKR xenotropic virus[23], which has been shown to appear only in TE cells derived from AKR mice older than 24 weeks.

The TE would then serve a dual role in the aged AKR; to trigger the cell into a susceptible state of differentiation and to supply the additional factors needed to initiate leukaemogenesis. Leukaemogenesis therefore seems to involve two or three distinct phases: (1) the infection with MuLV; (2) the necessary state of target-cell differentiation; and/or (3) additional unknown factors present in TE cells of aged AKR mice necessary to trigger leukaemic transformation. At present it is not possible to distinguish between the second and third possibilities. The long latent period needed for leukaemogenesis in the intact mouse might be required to generate such additional factors as the AKR xenotropic virus in the thymic microenvironment.

The *in vitro* system presented here makes feasible an analysis of the interactions of these factors in leukaemogenesis.

Hormone-dependent haematopoiesis in fibroblast-transformation ossicles

SUBCUTANEOUS transplantation of coarse powders of acid-insoluble matrix of the shafts of long bones of rat to allogeneic recipients results consistently in the formation of new bone through endochondral ossification[1]. Haematopoietic bone marrow develops in the newly formed ossicle in adolescent rats[2,3] and this experimental model is amenable to an investigation of hormonal control of initiation of haematopoiesis. Erythropoiesis is dependent on pituitary hormones[4,5] since hypophysectomy resulted in anaemia in all animal species which have been studied. Hypophysec-
Fig. 1 Photomicrographs of histological sections of transformation ossicles from control (*a*) and hypophysectomised (*b*) rats stained with haematoxylin and eosin. *a*, Haematopoietic cells on day 26 in a control rat. *b*, Scattered basophilic cells in a hypophysectomised rat. Hypophysectomy on day 0 (×250).

tomy caused a prompt regression of many stem-cell erythro-blastic leukaemias in rat[6]. We now report the profound influence of hypophysectomy on *de novo* erythropoiesis in matrix-induced transformation ossicles.

Dehydrated diaphyseal shafts of rat femur and tibia were comminuted and sieved. Powders with particle sizes of 74–420 μm were demineralised with 0.5 M HCl and extracted with water, ethanol and ether as described in ref. 1. This preparation is designated as 'transformant of fibroblasts (TF). Male rats, age 35–37 d, of Long–Evans strain were anaesthetised with ether. In sterile conditions TF (25–30 mg) was transplanted as a compact deposit into a subcutaneous pocket prepared by blunt dissection. The incision was closed with a metallic clip. As previous studies[2] have established the superiority of the thoracic site over that of the abdominal site for erythropoiesis, transplants were confined exclusively to the former anatomical location. In each rat there were two bilaterally symmetrical sites in the upper thoracic region. The day of operation was denoted day 0. Hypophysectomy was performed by D. Otway of the Hormone Assay Laboratory, Chicago, on day 0 unless otherwise indicated in the tables. At the time of collection of the transformation ossicles, the rats were anaesthetised and exsanguinated by cardiac puncture with a 19-gauge hypodermic needle followed by decapitation. The ossicles were dissected out and weighed. The weights of testis and spleen were recorded to confirm the completeness of hypophysectomy. The body weights of all the animals were recorded three times a week. The hypophysectomised animals lost weight whereas the control rats gained 3–4 g per day.

The histological sequences in response to subcutaneous implantations have been described in detail[2,3] and consist of the following stages in the control rats. On day 1 a planoconvex, button-like plaque was formed; it is a conglomerate of TF, fibrin network and polymorphonuclear leukocytes. On day 3 the plaque consisted of TF and invading fibroblasts. By day 4 there was close-range matrix–membrane interactions[3] and chondroblasts emerged on day 5 for the first time. Chondrocytes were abundant on days 7 and 8. With the incursion of capillaries on day 9 there began chondrolysis and osteogenesis. By day 12 an osseous conglomerate with cavernous spaces had formed. On day 14 extravascular islands of dark-staining haemocytoblasts were evident. With progressive differentiation the entire ossicle was filled with haematopoietic bone marrow replete with cells in the erythrocytic and granulocytic series and with megakaryocytes by days 23–25 (Fig.

Table 1 Influence of hypophysectomy on alkaline phosphatase and ^{59}Fe incorporation in transformation ossicles, femoral bone marrow and spleen

| | Alkaline phosphatase U g^{-1} Transformation ossicles | | Transformation ossicles | | ^{59}Fe incorporation (c.p.m. per mg tissue) Bone marrow | | Spleen | |

Alkaline phosphatase and ^{59}Fe incorporation into protein-bound haem was determined as described earlier[1]. All numbers represent mean±s.e. of 8 observations.
*Significant difference from control.

1a). Collection was routinely carried out on days 27–31 in our experiments, as haematopoiesis became fully functional at that time.

Bone formation was assayed by measuring the activity in the transplantation ossicle of alkaline phosphatase, an enzyme known to be intimately associated with ossification[7]. Hypophysectomy (hypox) delayed but did not prevent the formation of the osseous conglomerate. The maximal concentration of alkaline phosphatase, ∼ 60 U g^{-1}, was similar (Table 1) in the ossicles of intact and hypox hosts. But the peak of enzyme activity in intact rats was attained on day 10 whereas in hypox rats, the concentration of alkaline phosphatase in the ossicles was a maximum (Table 1) on day 21.

Hypophysectomy profoundly inhibited the development of haematopoiesis. On day 27, the transplantation ossicles in normal hosts were dark red with an abundance of maturing blood cells (Fig. 1a). In contrast, the ossicles in hypox rats were pale pink in the gross on day 27 and the marrow consisted exclusively of scattered individual basophilic cells (Fig. 1b), presumably haemocytoblasts; maturation of blood cells was absent. The incorporation of ^{59}Fe into protein-bound haem, an indicator of erythropoiesis, was barely detected in transformation ossicles of hypox rats and was significantly lower than the controls in the femoral bone marrow (Table 1). The spleen of hypox rats was tiny and pale pink in the gross; the spleen of control rats was larger and had a dusky red colour (Table 2). The ^{59}Fe incorporation in the spleen was significantly depressed following hypophysectomy (Table 1).

In another series of experiments the day of hypophysectomy was varied to determine if a delay in removal of the pituitary would improve the ^{59}Fe incorporation in transformation ossicle, bone marrow and spleen It was found that hypophysectomy 9 to 26 d before collection resulted in a profound decrease in erythropoiesis as revealed by ^{59}Fe incorporation (Table 2).

The results demonstrate that the onset of haematopoiesis

Table 2 Decline of ^{59}Fe incorporation in transformation ossicles, femoral bone marrow and spleen following hypophysectomy

| Hypophysectomy day | ^{59}Fe incorporation (c.p.m. mg^1) | | |
	Ossicle	Bone marrow	Spleen
	Hypophysectomised rats		
0	2±0.4*	179±50*	10±1*
8	1±0.4*	165±45*	10±1*

Control and hypophysectomised rats were littermates. Autopsy was performed 26–31 d after transplantation of bone matrix. Hypophysectomy was performed on the days indicated. ^{59}Fe incorporation into protein-bound haem was determined as described[1]. All values represent mean±s.e. of 8 observations.
*Significant difference from control.

is critically dependent on pituitary hormones. The availability of a hormone-dependent differentiating haematopoietic system in post-foetal life makes it possible to integrate the factors regulating hormone-dependent and hormone-independent haematopoiesis.

Depletion of L-cell sterol depresses endocytosis

THE engulfment of droplets of fluid, from the surrounding medium (endocytosis or pinocytosis), represents a phenomenon of the plasma membrane of many mammalian cells[1-3]. The physiological significance of the process is not well understood although circumstantial evidence seems to suggest that it is necessary for normal functions of certain cell types. Steinman *et al.*[4] have established the qualitative and quantitative aspects of endocytosis and have demonstrated that a variety of cells directly interiorise soluble proteins (for example, horseradish peroxidase) by invagination of the plasma membrane without previous binding of the proteins to cell-surface receptors. Cholesterol is a prominent constituent of the plasma membrane of mammalian cells, and its role in many complex functions of the cell membrane is just beginning to be understood. It buffers the 'fluidity' of the plasma membrane, increasing the viscosity at high temperatures and impeding the transition into the gel state at reduced temperatures[5-7]. Through its action on membrane fluidity, or possibly more directly, it affects specific functions of the membrane such as ion transport and enzyme activities[8]. With these manifold effects of cholesterol on membrane structure and function in mind, we investigated the effect of altered sterol concentration on the ability of cultured cells to carry out endocytosis, to clarify further the role of cholesterol in membrane-dependent cytological functions.

The procedures we used to investigate the role of membrane-associated sterol in endocytosis are based on our finding that certain oxygenated derivatives of cholesterol (for example, 25-hydroxycholesterol and 7-ketocholesterol) are potent inhibi-

Fig. 1 Rate of endocytosis in L cells after treatment with various inhibitors of sterol synthesis. The culture medium contained 25-hydroxycholesterol 1 μg ml^{-1} (△), 20α-hydroxycholesterol, 1 μg ml^{-1} (▲), 7-ketocholesterol 1 μg ml^{-1} (■), 6-ketocholestanol 1 μg ml^{-1} (×) or cholesterol 100 μg ml^{-1} (●). Control cultures contained 50 μl 5% bovine serum albumin (BSA) solution used to suspend the sterols (○). The cultures were incubated for 16 h at 37 °C. Each point represents the mean ± s.e of 3–5 cultures.

tors of sterol synthesis in cultured cells[9]. The inhibitory sterols specifically depress the activity of 3-hydroxy-3-methylglutaryl-(HMG)-CoA reductase, the regulatory enzyme in the sterol synthesis pathway. Treatment of L cell (mouse fibroblast) cultures with these inhibitors for periods longer than 1 d reduces the sterol (desmosterol) content of the cells and their plasma membranes to about one-half of the original level (A.A.K. and H.W.C., unpublished and ref. 10). Cells which are depleted of sterol do not grow or divide unless an exogenous, non-inhibitory sterol (cholesterol or desmosterol) or a sterol precursor (mevalonate) is supplied[10].

L cells were grown in Waymouth's MB 752/1 medium supplemented as described previously[9]. The cells were seeded in 35-mm plastic dishes of 2-ml portions containing a total of 0.7 × 10⁶ to 2 × 10⁶ cells depending on the type of experiment. Different inhibitors of sterol synthesis (6-ketocholestanol, 7-ketocholesterol, 20α-hydroxycholesterol, or 25-hydroxycholesterol) were added to the medium (2 ml) in 50 μl of a 5% solution of crystallised bovine serum albumin (BSA) containing 10% ethanol[9] so that the final concentration of sterol was 1 μg ml^{-1}. Control cultures received 50 μl of the albumin–ethanol solution.

Cellular endocytosis was assayed as described by Steinman *et al.*[4]. Briefly, L cells were incubated for various periods of time with sterols and/or their precursors and were then reincubated for 1–3 h with horseradish peroxidase (Sigma, type II) dissolved in fresh culture medium (1 mg ml^{-1}). The peroxidase-containing medium was removed by suction, the cultures were gently washed five times with phosphate-buffered saline, and then reincubated for 50 min at 37 °C in Waymouth MB 752/1 medium to remove all non-ingested peroxidase. The cells were then lysed by incubation with an aqueous solution of Triton X-100 (0.05% v/v) for 2 h at room temperature. The amount of peroxidase in the lysate was determined as described by Steinman *et al.*[4]. These authors have shown that: there are no cell-surface receptors for the probe (peroxidase); the rate of endocytosis increases linearly with temperature; endocytosis is dependent on ATP

generated by glycolysis and the respiratory chain; and the process is independent of the cell cycle.

Figure 1 shows the effects of incubating various inhibitors of sterol synthesis with L cells for 16 h on the ability of the cells to carry out endocytosis. 20α-hydroxycholesterol and 25-hydroxycholesterol depressed the rate of endocytosis by 42 and 54% respectively, whereas 6-ketocholestanol and 7-ketocholesterol were less active. The relative potencies of these sterols as suppressors of endocytosis were similar to their reported potencies as inhibitors of sterol synthesis[9]. Purified cholesterol at a high dose (100 μg ml^{-1}) had no effect on endocytosis. The rate of uptake of peroxidase in the control cultures averaged 167 ng per mg cellular protein per h. This corresponds approximately to 0.0049% of the administered peroxidase per 10⁶ cells h^{-1}, a value which is slightly higher than the corresponding range of 0.0032–0.0035% reported by Steinman *et al.*[4] in another subline of L cells.

The effect of 25-hydroxycholesterol on endocytosis as a function of time during which the inhibitor was incubated with the cultures is shown in Fig. 2. Endocytosis was quantitatively affected as early as 6 h after addition of 25-hydroxycholesterol. After 12 h the level of endocytosis had reached a minimum level which remained unchanged for the following 36 h. The slope of the curve in Fig. 2 appears to be somewhat steeper than the decline in the concentration of membrane sterol in other similar experiments and was preceded by the disappearance of HMG-CoA reductase activity and the loss of sterol synthesis (ref. 9 and A.A.K. and H.W.C., unpublished). The effect of incubating L cells for 16 h with various concentrations of 25-hydroxycholesterol is shown in Fig. 3. Endocytosis was affected by 25-hydroxycholesterol at a concentration as low as 0.05 μg ml^{-1} (10^{-7} M) and maximal depression of endocytosis was reached at concentrations of 0.5 μg ml^{-1}.

L cells, in which HMG-CoA reductase activity is depressed by 25-hydroxycholesterol, are able to synthesise sterols from exogenous mevalonate, which is the product of the reaction catalysed by the reductase. In similar conditions they are not able to synthesise sterols from acetate or HMG[9,10]. Table 1 shows that the addition of exogenous mevalonate or cholesterol resulted in the maintainance of a normal level of endocytosis in the presence of 25-hydroxycholesterol. In other experiments (not shown) acetate or HMG did not relieve the inhibitory effect of 25-hydroxycholesterol. The recovery of endocytosis with meva-

Fig. 2 Time course of inhibition of endocytosis by 25-hydroxycholesterol. The culture medium contained 5% foetal calf serum (●), 25-hydroxycholesterol 1 μg ml^{-1} in 50 μl 5% BSA solution (▲) or 50 μl BSA solution (○). After the incubation periods indicated, rates of endocytosis over a 2-h period were determined. Values shown represent the mean ± s.e. for 3 cultures.
Fig. 3 Effect of incubating L cells with varying concentrations of 25-hydroxycholesterol on the rate of endocytosis. 25-hydroxycholesterol was added to the culture medium in 50 μl 5% BSA solution. After incubation for 16 h with the inhibitor, rates of endocytosis were determined over a 2-h period. Values shown represent the mean ±s.e. for 3 cultures.

Ionate supports our previous findings (refs 9 and 10 and A.A.K. and H.W.C., unpublished) that the inhibitory sterols do not have effects other than those resulting from the suppression of HMG-CoA reductase and sterol synthesis.

The possibility that incubation of L cells with the inhibitory sterols may have depressed the level of intracellular ATP was examined by comparing the concentration of ATP in cultures incubated with or without 25-hydroxycholesterol. Using the luciferin–luciferase assay[11,12], we did not detect any significant differences in the concentration of ATP between control cultures and cultures treated with 25-hydroxycholesterol for as long as 40 h. As the cultures approached confluency the level of ATP dropped in both groups. A diminished ATP level in confluent cell cultures has been reported by others[4].

These results, indicating that cells which are deficient in sterol are unable to carry out endocytosis at normal rates, emphasise the important functional role of cholesterol in the plasma membrane. Dianzani *et al.*[13] have demonstrated that increased amounts of cholesterol in the plasma membrane of macrophages depresses phagocytosis—that is, endocytosis of particulate material. If phagocytosis in macrophages and endocytosis in cultured L cells are accomplished by the same basic mechanism, then our results, together with their observations, indicate that the concentration of cholesterol in mammalian cell membranes must be maintained within a fairly narrow range to ensure their

proper biological functioning. Our results may also be related to certain observations of altered functioning of fibroblasts from patients with familial hypercholesterolaemia. Since fibroblasts from these patients cannot take up low density lipoprotein (LDL) at a normal rate[14] it would be of interest to determine whether or not there is any abnormal concentration of cholesterol in the plasma membranes of these cells. Our observations also suggest an alternative interpretation of data published by Brown and Goldstein[15] which showed a diminished uptake of LDL in normal human fibroblasts that had been preincubated with 25-hydroxycholesterol or LDL. Since both surface-bound and internalised LDL were included in the measurement of LDL 'binding' it could be argued that the effect of 25-hydroxycholesterol was to diminish endocytosis rather than to reduce the number of LDL receptors as originally suggested by Brown and Goldstein.

It is established that cholesterol has an important role in the regulation of the activity of membrane-localised Na^+/K^+ ATPase in mycoplasma[9] and in mammalian cells[8,16,17]. Thus, changes in endocytosis and in ion transport both may contribute to the inhibition of DNA synthesis that we have observed in L cells and in lectin-stimulated lymphocytes treated with inhibitors of sterol synthesis (ref. 18 and A.A.K. and H.W.C., unpublished). Whether the continuous uptake of solutes and membrane material is necessary for the maintenance of normal cell functions needs further clarification. The present study suggests, however, that cholesterol is a critical functional as well as structural unit in the plasma membrane and that its depletion results in the modification of specific membrane-dependent cellular functions.

This study was supported by the NCI. We thank Mrs Jan Marshall for assistance.

25-Hydroxycholesterol (1 μg ml⁻¹)	109.0±26.9 (7)	45	P<0.01
25-Hydroxycholesterol (1 μg ml⁻¹)+ mevalonic acid (0.5 mg ml⁻¹)	229.2±20.8 (2)	95	NS
25-Hydroxycholesterol (1 μg ml⁻¹)+ cholesterol (100 μg ml⁻¹)	250.0±27.8 (2)	103	NS

*Cells were cultured for 36 h in the presence of the listed compounds. †The rate values (mean±s.e. for 3–4 cultures) were based on measurements obtained between the first and second hour of incubation with horseradish peroxidase. Numbers in parentheses indicate the number of experiments. The *t* test results indicate the probability of a significant difference between control and experimental values.

Duplication of biochemical changes of Huntington's chorea by intrastriatal injections of glutamic and kainic acids

SYSTEMIC administration of large doses of L-glutamate to immature animals causes degeneration of neurones in the retina and the arcuate nucleus. Olney *et al.*[1] reported that intracerebral injections of the more potent excitatory analogues of glutamate, in particular kainic acid, caused rapid degeneration of certain dendritic and somal structures in the injected area. Presumably the degeneration is related to the ability to bind the "excitotoxic" agent, with necrosis resulting from a sustained increase in membrane permeability.[3] ³H-kainic acid binds more strongly to striatal tissue than to any other area of rat

brain tested[2]. This lends some support to Spencer's theory[3]—based on antagonism of cortical excitation of striatal neurones by diethyl glutamate—that the massive corticostriatal pathway is glutaminergic. If Huntington's chorea were an excitotoxic phenomenon resulting from chronic overstimulation of glutamate receptors, striatal neurones in particular would be affected because of heavy glutaminergic input. This hypothesis is not readily tested by simple measurement of glutamate in choreic tissue because glutamate is a precursor of γ-aminobutyric acid (GABA) and is also involved in other metabolic activities. As one potential test of this hypothesis, we have injected 1 μl of either kainic acid or L-glutamic acid dissolved in isotonic saline directly into the extrapyramidal nuclei of rats. Injection into the striatum produced local enzymatic changes duplicating those reported in Huntington's chorea.

The sites of injection and the coordinates by the Konig and Klippel atlas[4] were: caudate, AP 8.38, L 2.8, DV +0.2; ventrolateral thalamus, AP 4.75, L 2.8, DV +1.4; and substantia nigra, AP 2.18, L 2.1, DV −2.2. Injections were into 300-g male Wistar rats under sodium pentobarbital anaesthesia.

The extrapyramidal system has neurones containing dopamine, acetylcholine and GABA. The state of these neurones in extrapyramidal disorders such as Huntington's chorea and Parkinson's disease is reflected by the level of the enzymes for transmitter synthesis[5]. Therefore we measured the levels of tyrosine hydroxylase (TH), choline acetyltransferase (CAT) and glutamic acid decarboxylase (GAD) in the rat brain extrapyramidal nuclei after the injections.

After 2 or 3 d, the rats were killed by cervical fracture, the brains were removed rapidly, and the desired nuclei were dissected and homogenised in 0.25 M sucrose. Aliquots of these sucrose homogenates were used for enzyme determinations by the radioactive methods used in the study of enzyme activities in human brain tissue[5]. Protein was determined by the Folin–Ciocalteau method.

The biochemical results are shown in Tables 1 and 2. After injections of 5 nmol of kainic acid (Table 1), the largest changes were observed with striatal injections. There were large losses of GAD and CAT (to 34% and 36%, respectively) in the striatum itself, and there was a smaller decrease of GAD in the substantia nigra (to 66%). There was also a significant increase (to 128%) in striatal TH. With comparable thalamic injections, there were no significant enzyme changes in the substantia nigra and caudate, and only a mild drop in thalamic GAD. Nigral injections also produced no significant striatal changes, although there was a slight drop in nigral TH.

When the amount of kainic acid injected into the caudate was reduced to 2.5 nmol, the effect was reduced, and 1 nmol had no effect. A dose of 50 nmol of L-glutamic acid produced the equivalent effect of 2.5 nmol of kainic acid (Table 2).

Table 1 Some enzyme activities on the side injected with 5 nmol of kainic acid as a percentage of those on the control side

Area injected	Area analysed		
Enzyme	Striatum	Thalamus	Substantia nigra
Caudate (6)			
GAD	34 ± 3 %*	107 ± 16 %	66 ± 14 %†
CAT	36 ± 8 %*	113 ± 16 %	119 ± 21 %
TH	128 ± 9 %†	91 ± 12 %	100 ± 14 %
Thalamus (3)			
GAD	90 ± 15 %	72 ± 11 %†	96 ± 6 %
CAT	109 ± 12 %	114 ± 15 %	—
TH	94 ± 11 %	92 %14 %	—
Substantia nigra (4)			
GAD	107 ± 9 %	106 ± 9 %	125 ± 27 %
CAT	90 ± 10 %	71 ± 8 %†	107 ± 19 %
TH	87 ± 14 %	70 ± 20 %	73 ± 9 %†

Control values were the same as found in uninjected animals and averaged for the striatum (in μm per h per 100 mg protein): 15.5 for GAD; 31.3 for CAT and 0.175 for TH. Protein content was not significantly different in the injected as compared to the control samples. Data given as mean ± s.e., number of animals in parentheses.
*$P < 0.001$.
†$P < 0.05$.

Table 2 Enzyme levels in striatum on injected side as percentage of those on contralateral side

Material injected	CAT	GAD	TH
Kainic acid, 2.5 nmol	81 ± 4 %*	84 ± 6 %*	111 ± 8 %
Kainic acid, 1 nmol	100 ± 8 %	91 ± 7 %	113 ± 12 %
L-glutamic, 50 nmol	82 ± 5 %*	83 ± 4 %*	114 ± 6 %

Figures are mean ± s.e. Four rats were used in each case.
*$P < 0.05$.

The reduction in striatal CAT, and striatal and nigral GAD, with sparing or enhancement of TH, parallels the biochemical findings in Huntington's chorea[5–7]. Thus, these excitotoxic injections produced a biochemical model of the disease. They also produced marked physical manifestations.

Rats injected with 5 nmol of kainic acid into the left caudate almost immediately developed diarrhoea and stopped grooming. By the third day, they were bleeding from their nose and urinary tract. When injections were made in the thalamus there was similar, though lesser bleeding, and loss of grooming. Injections into the substantia nigra did not cause bleeding but did cause the mouth and eyes to water. Rats given the injections in either the left caudate or left substantia nigra held their heads tilted markedly to the left with their bodies hunched. Rotation was not prominent, however, except when injections were made into the thalamus: then each rat, on awaking from the anaesthesia 30–60 min after injection, rolled over and over slowly to the left while the tail was held stiffly erect and rotated clockwise like a propeller and the head was tilted to the left. After 2 or 3 h rolling ceased and the animal alternately stood erect and pirouetted, also clockwise. Subsequently, the rat repeatedly circled the plastic cage in a clockwise direction, rubbing against the wall and with the head still tilted to the left. These movements had stopped by the next day.

Rats injected with 1 or 2.5 nmol of kainic acid or with 50 nmol of L-glutamic acid into the caudate showed no dramatic effects.

With the 5-nmol injections of kainic acid, two of eight caudate-injected rats died between the second and third day, as did three of six thalamus-injected rats. There were no deaths observed in the substantia nigra-injected rats. All three rats that received this dose of kainic acid in the globus pallidus died within 24 h.

The injections were always unilateral and no behavioural tests were carried out. To establish whether the excitotoxic model of Huntington's chorea truly parallels the disease, further exploration of the motor and behavioural effects is needed.

The excitotoxic hypothesis of Huntington's chorea might also help to explain the phenomenon of tardive dyskinesia. This motor disorder is characterised by choreiform movements which are hard to distinguish from Huntington's chorea and which appear after long term therapy with dopaminergic blockers. The dopaminergic nigro-striatal tract is believed to be inhibitory towards striatal interneurones, and administration of neuroleptics apparently releases cholinergic interneurones[8,9]. This removal of inhibition could result in normal excitatory input from the cortex, possibly of a glutaminergic nature, becoming excitotoxic and gradually destroying striatal interneurones.

Stereoselective effects of the potentially neuroleptic rigid spiro amines

WE HAVE reported the synthesis and pharmacological effects of a novel series of tetracyclic spiro compounds structurally related to the tricyclic antidepressants[1]. In contrast to the common tricyclic antidepressants, the terminal amino group of the spiro compounds has restricted mobility. As expected, some of these compounds have antidepressant properties in model systems, for example they are potent blockers of the neuronal uptake of noradrenaline in the central nervous system. But the compounds containing a chlorine atom in the tricyclic moiety have a neuroleptic profile in animal tests. 3-Chloro-10,11-dihydro-N,N-dimethylspiro-[5H-dibenzo[a,d]cycloheptene-5,1'-cyclohex-2'-ene]-4'-amine, structure (I), is particularly interesting in this respect. The cyclohexene ring in this structure is located perpendicularly to the tricyclic ring system and as a consequence the amino group can occupy a position either *cis* or *trans* to the chlorine-containing part of the tricyclic ring system. Furthermore, the *cis* and *trans* isomers can be resolved into enantiomers as the molecule contains two chiral centres (marked with asterisks in structure (I)). Several studies have yielded re-

(I)
sults to favour the view that neuroleptic drugs act as dopamine (DA) antagonists in the brain[2,3] and that the DA receptor blockade is rather well correlated with their antipsychotic efficiency[4-6]. The neuroleptics seem to block chiefly postsynaptic DA receptors, particularly in striatal[7] and mesolimbic[8] DA areas of the brain. The rigid nature of the isomeric tetracyclic spiro amines of structure (I), and the possibility of stereospecific pharmacological effects make these compounds interesting tools for an investigation of the structural requirements for DA receptor blockade and for studies on DA receptor topology.

The *cis* and *trans* isomers have now been separated in the following way. A substance, melting point 245–246 °C (hydrochloride), prepared essentially as described previously[1], was converted to the corresponding oxalate. Fractional crystallisation of this oxalate gave partial separation. Conversion to the hydrochlorides and renewed crystallisation resulted in the pure isomers. These are referred to as the α isomer (melting point 257–259 °C (hydrochloride)), and the β isomer (melting point 226–228 °C (hydrochloride)).

The separation was monitored by nuclear magnetic resonance spectroscopy. Comparison of the spectra of the pure isomers with that of the substance used in our previous

Table 1 Effects on apomorphine stereotypies in the rat

*Astra's internal code number.
Apomorphine (2 mg kg^{-1}) was administered intraperitoneally to male Sprague–Dawley rats (150–200 g). The test compounds were injected intraperitoneally 30 min before apomorphine in five doses (six animals per dose). The stereotypies were scored according to Costall and Naylor[11]. ED_{50} refers to the dose of the test compounds which reduces the stereotypies by 50% 20 min after apomorphine administration.

work[1] showed that the latter consisted of a mixture of about equal parts of α and β isomers.

The α and β isomers have been resolved using the optically active mandelic acids and di-p-toluoyltartaric acids. The antipodes of the two isomers have specific rotations of 148° (hydrochloride in ethanol) and 204° (maleate in chloroform), respectively.

The isomers were evaluated for their ability to inhibit apomorphine-induced stereotypies in the rat; this is a selective and sensitive test for neuroleptic activity[9]. Apomorphine stereotypies seem to be a result of DA receptor stimulation in the brain, which makes this test an *in vivo* technique for measuring DA receptor blockade[10].

The results of the apomorphine test show differences in activity between the isomers (Table 1). The *cis–trans* mixture of the spiro amine (I) is a potent blocker in this test. The pharmacological activity resides chiefly in the β isomer which is about as potent as chlorpromazine. Studies on the enantiomers revealed a further difference in activity. Only one of the enantiomers, (−)-β, was found to be active in this test, being three or four times as potent as chlorpromazine. Further evidence for the specificity of this enantiomer as a blocker of the DA receptor was provided by DA turnover studies in the rat. It is well known that neuroleptic drugs accelerate DA turnover, probably due to an increase in DA neuronal activity as a result of DA receptor blockade[2-6]. Of the two pairs of enantiomers, only the (−)-β isomer increased DA turnover in the brain.

In studies of thioxanthenes, the *cis* isomers, were found to be considerably more potent than the corresponding *trans* isomers in various tests for neuroleptic activity[12,13]. It may therefore be postulated that the active tetracyclic spiro amine (−)-β has the *cis* configuration. The stereochemistry of the isomers is being investigated by X-ray diffraction methods.

We conclude that there are strict stereochemical requirements for a potent and selective blocker of the DA receptor. The compounds discussed here apparently fulfil these requirements.

Ca²⁺-dependent arrest of cilia without uncoupling epithelial cells

IN CERTAIN ciliated epithelia, for example, mussel gill lateral cell epithelium, metachronally coordinated ciliary beat can be arrested systematically, either after nervous[1] or local stimulation, for example by laser microinjury[2,3]. In the latter case, the velocity of spread of arrest, its extent and decremental character suggest that the response depends on electrotonic coupling of the gill cells[3]. The lateral cells are coupled by extensive septate junctions and small gap junctions[4], more basally located, which may act in a manner homologous to electrical synapses of nerve and muscle cells[4-7]. Although intracellular microelectrode recordings of lateral cell depolarisation accompanying arrest after branchial nerve stimulation have been made in *Mytilus*[1], there are no reports of microelectrode studies of cell coupling in gill cells. We have used experimentally-induced spreading arrest to monitor the state of coupling in the lateral cell epithelium of a freshwater mussel (for example, *Elliptio complanatus*).

Lateral cell cilia are arrested by an increase in cytoplasmic calcium ion concentration. Arrest does not spread past a focus of local damage in *Mytilus* gill in the absence of Ca²⁺ in the bathing medium[3]. Furthermore, when gill filaments from freshwater mussels are placed in 12.5 mM CaCl₂, the cilia beat metachronally; when a divalent cation ionophore A23187 is added, arrest occurs; arrest does not occur by ionophore in the presence of Na, K⁺ or Mg²⁺, without Ca²⁺ (ref. 8).

An increase in local Ca²⁺ concentration causes coupled epithelial cells of *Chironomus* salivary gland to uncouple[8], but Rose and Loewenstein[14] have shown that Ca²⁺ influx into a cell is often quenched by various cell components, so that Ca²⁺ concentration in the cytoplasm may change only minimally, if at all, in parts of the cell distant from the site of influx. It may therefore be that even when Ca²⁺ is entering a cell at the apical surface, the effective concentration of Ca²⁺ at the cell junctions remains low and the cells remain coupled. This seems to be a necessary conclusion in many circumstances, for example, during cardiac
Fig. 1 Design of summation experiment. A gill filament beating with good metachronal waves (η-like structures) selected (a). At t = 0, a laser hit (lesion no. 1) made; within a few seconds along a defined field (length about 1 mm, arrows) metachronism ceased (b). The initial recovery to either side of the field was measured (t_R and t_L) (c). The gill was repositioned so that a second hit (lesion no. 2) could be made about 0.25 mm away from a returning wavefront (d). At t_H, this hit divided the gill filament into regions A, B and C (e). The effect on recovery was measured by the reappearance of metachronism to either side of the field (t_{L2} and t_{R2}). The geometry varied slightly in individual experiments. Usually region A recovered completely (t_A) (f); then region C (t_C) (g) and finally region B recovered (t_B) (h) with a time course given by equation (3) (see text). Cells damaged by the hits never recovered.

muscle contraction, but as far as we know it has not been demonstrated precisely with any system. We report here that mussel gill cells remain coupled during ciliary arrest.

Gills of freshwater mussels (Carolina Biological Supply Co., Gladstone, Oregon) were excised and placed in 12.5 mM CaCl₂; they usually remained fully active for many

hours with almost 100% metachronism. Small pieces of active gill were placed on a depression slide containing three or four drops of 1% blue dye FDC No. 1 in $CaCl_2$, for laser microdisruption as described before[2,3,11]. A pulsed ruby laser microbeam was focused near the base of the beating cilia at a selected point to produce a focal lesion of about $30\,\mu m$ diameter (Fig. 1a and b). The timing of all subsequent events (Table 1) was measured from the moment of microbeam irradiation (t_0).

The lesion induced arrest of ciliary beat which spread, as expected, along the gill filament up to about 1 mm on either side of the hit (Fig. 1b)[2,3]. Characteristically, metachronism was first reactivated in the cells most distant from the hit. The time that metachronism reappeared in a defined field to either side of the lesion (t_R and t_L) was recorded (Fig. 1c and d). Between the original lesion and the returning metachronal wave cilia were still arrested. The gill was then moved so that the laser microbeam was focused near the centre of the arrested field to one side of the lesion, approximately 0.25 mm away (10 cell lengths) from the returning metachronal wavefront, so as to produce a second lesion at this point (Fig. 1d). The gill filament was thus divided into three regions: A, B, and C, where B lies between the two lesions, and C is beyond the second lesion (Fig. 1e).

In about 90% of experiments, the second lesion reintroduced arrest in region C (Fig. 1e). Experimental failure probably reflects our inability to focus the laser accurately and the consequent variability of microbeam strength at lateral cell sites. This also accounts for much of the variability in the data, shorter times probably reflecting weaker hits. We measured the time after the second hit when metachronism first reappeared in region C (t_{R2-H}) (Fig. 1f). Typical data are given in Table 1; recovery was delayed on the average by 26.5 s (31 experiments).

To produce such delay, the stimulus produced by the second lesion must apparently have spread through an average of 10 lateral cells whose cilia are arrested, before reaching the reactivating cells where we observed secondary arrest. This supports the conclusion that the cells with arrested cilia were still coupled, but does not rule out an alternative possibility that cells (for example, the intermediate cells) adjacent to the column of arrested lateral cells provided the coupling pathways, being coupled to one another and to the reactivating cells at the time of the second hit.

In contrast, the second lesion reintroduced arrest in region A, beyond the first lesion, in only 20% of experiments; that is, recovery (t_{L2-H}; Table 1) is not delayed (Fig. 1e). We interpret this to mean that lesion No. 1 usually destroyed the physical integrity of the gill filament, so that the column of cells beyond the lesion to the left was uncoupled from the column of cells to the right. Therefore, the stimulus produced by the second lesion should have affected the cilia of regions B and C but not those of region A. If this is correct, the proability is greatly reduced that coupling that affects the lateral cell metachronism can occur through an alternate pathway adjacent to the lateral cells.

We have demonstrated conclusively that cells with arrested cilia are still coupled, at least as defined by the ability to respond to a second distant stimulus, by measuring the times for complete recovery in regions, A, B and C (t_A, t_B and t_C, respectively; Fig. 1f, g and h). If arrested cells are uncoupled, we would expect recovery in region B to have been unaffected by the second lesion so that t_A and t_B would have been approximately equal. This was not the case (Table 1). If arrested cells are coupled, then region B would have been affected by the second hit, so that $t_B > t_A$ because of the induced recovery delay. Two simple explanations consistent with coupling were that (1) t_B and t_C are equal or (2) that region B would have recovered as if the hits were additive.

The first laser hit presumably produces a stimulus that enables sufficient Ca^{2+} from the bathing fluid to enter the apical surfaces of cells near the lesion to induce ciliary arrest in sequential fashion. Our results demonstrate that the pathway of coupling remains functional after ciliary arrest, although it is readily interrupted by a break in epithelial integrity. Our best explanation of the summation effect in the region between the two hits is that (1) the second hit produces further Ca^{2+} influx into the coupled chain of cells with arrested cilia and that (2) the recovery times measured depend on Ca^{2+} being pumped out of the cells at a constant rate such that when free Ca^{2+} falls below a critical concentration, metachronism reappears. If regions B and C are of approximately equal lengths and the stimulus is exponentially decremental with a decay constant of about 0.3mm, then we would expect that

$$t_B = t_A + \text{(effect of second lesion)} \qquad (1)$$

and that the effect of the second lesion is related to t_C in that

$$t_C - t_H = \text{(effect of second lesion)} + 0.37 t_A \qquad (2)$$

so that (3)

$$t_B = 0.63 t_A + t_C - t_H \qquad (3)$$

Both in individual experiments and on average ($P > 0.3$) equation (3) seems empirically valid (Table 1). This explanation supports and extends findings of Rose and Loewenstein[10] in that it requires the actions of Ca^{2+} in these conditions to be restricted largely to those in the immediate locale of the point of influx of the ion into the cytoplasmic matrix of the cell, that is to the cilia and not to the junctions.

Nervous inhibition of corpora allata by photoperiod in *Pyrrhocoris apterus*

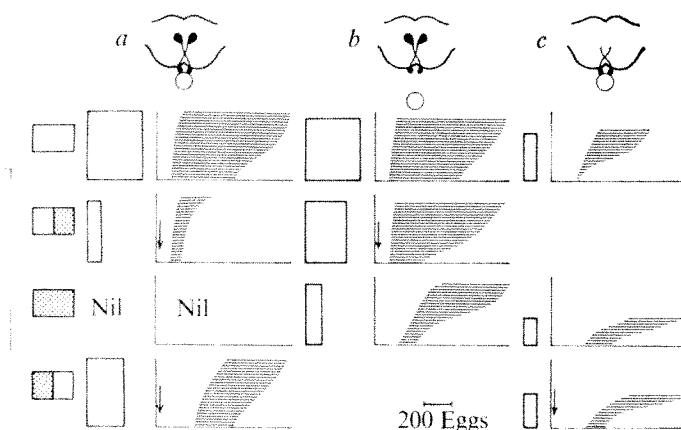
PHOTOPERIOD governs reproduction in many insect species with adult diapause. The nervous and neuroendocrine systems mediate the impact of the environment on ovarian functions. It has been suggested that the daylengths promoting diapause prevent secretion of the activation hormone (most probably a complex of neurohormones) from the pars intercerebralis (PI) of the brain. Without this hormone the corpora allata (CA) do not secrete the gonadotropic hormone and reproduction is arrested[1-3]. It has been shown, however, that other physiological conditions such as pregnancy[4], fasting[5], or lack of mating[6] produce an inhibitory effect of the brain on the CA through the nervi allati. The inhibition is probably mediated by a nervous centre situated close to the neurosecretory cells of the PI. We show here that the photoperiod that promotes diapause arrests reproduction by a double mechanism, the


Fig. 1 Schematic representation of the effect of denervation of corpora allata and extirpation of pars intercerebralis on reproductive activity. The first column of oblongs indicates photoperiods. Open, long day (LD 18 : 6); shaded, short day (LD 12 : 12). The three series of oblongs and graphs represent: *a*, sham operations (*n* = 20, 13, 35, 30); *b*, transections of nervi allati (*n* = 28, 17, 18); *c*, extirpations of pars intercerebralis (*n* = 10, 25, 44). Oblongs represent fecundity; width, eggs per female; height, % ovipositing females. Shaded area denotes length of oviposition period in days; horizontal axis, % ovipositing females (length of axis = 100%), vertical axis, time (length of axis = 50 d). Arrows, change of photoperiod.

suppression of humoral stimulation and the inhibition of the CA through the nerves. The effect of photoperiod is mediated by the pars intercerebralis.

We have studied the role of the nervi allati and centres in the PI in the regulation of the secretory activity of the CA in females of *Pyrrhocoris apterus*, under long- and short-day regimes. This species exhibits a facultative diapause controlled very regularly by the photoperiod; long daylengths have a stimulatory effect on the CA and reproduction, whereas short daylengths are inhibitory. This enables us to study both the stimulatory and inhibitory mechanisms regulating the activity of the CA. Experimental females were reared individually in Petri dishes on linden-seed at 26±2 °C and in long-day (18:6 h of light : darkness) conditions or short-day (12:12) conditions respectively. Transection of the nervi allati and extirpation of the PI were performed through an incision of the neck membrane[7]. Since size is not a reliable sign of CA activity in *P. apterus*[8], the activity of the CA was evaluated by the rate of oviposition.

In females kept permanently under long-day conditions the denervation of the CA did not affect reproduction and therefore the activity of the CA. The same operation disturbed the inhibitory effect of short daylengths however. The control (sham-operated) females stopped oviposition soon after the transfer from long- to short-day conditions, or did not begin to oviposit when reared from the eggs at short daylengths. In the first case, transection of the nervi allati resulted in a considerable prolongation of the oviposition period and increased fecundity. In the second case, the females with denervated CA had at the least low reproductive activity (Fig. 1*a*, *b*). This demonstrates that the inhibitory signal of short daylengths arrives at the CA through the nervi allati. It is interesting that transection of the nervi allati in diapausing *Leptinotarsa decemlineata*[1] or *Anacridium aegyptium*[3] had no effect. Transection of the nervi allato-suboesophagealis slightly activated the CA in *L. decemlineata*, but this activation was not sufficient to induce oviposition[1].

Extirpation of the PI in *P. apterus* resulted in low reproductive activity regardless of the photoperiod used (Fig. 1*a*, *c*). Since sham-operated females were very fecund under long-day conditions and they did reproduce under short-day conditions, the PI seems to mediate the optimal stimulation of reproduction

by long daylengths and also its complete inhibition by short daylengths.

In long-day conditions the PI stimulated reproduction not only through the CA but also by other pathways; the treatment of females without PI with a juvenile hormone analogue accelerated the maturation of oocytes in the first reproductive cycle, but it did not increase the overall fecundity[9]. As denervation of the CA did not affect reproduction in long-day conditions we assume that the PI stimulates the CA by way of the haemolymph. In short-day conditions, however, the PI seems to inhibit the CA through the nerves; denervation of the CA stimulated reproduction in a similar way to the extirpation of the PI. Similar rates of reproduction in both these cases also indicate that at short daylengths the PI does not exert the stimulatory effect as observed at long daylengths. The reason why denervated CA are more active in long-day females than in short-day females[10] can probably be explained by the lack of humoral stimulation from the PI in short-day conditions.

The findings described enable us to propose a hypothetical model of photoperiodic regulation of reproduction in *P. apterus* (Fig. 2). According to this model the PI contains both stimulatory and inhibitory centres. The photoperiod regulates the relative activities of these two centres. In long-day conditions activation of the stimulatory centre predominates which results in a highly active CA and reproduction. Conversely, in short-day conditions the activity of the inhibitory centre prevails, the CA are inactivated and females do not oviposit at all (Fig. 2*a*). The denervation of the CA does not affect the reproductive activity of long-day females for the stimulation of the CA is humoral. The same operation, however, induces oviposition in short-day females, because the inhibitory signal does not arrive at the CA through the sectioned nervi allati. Reproductive activity is low as the action of the stimulatory centre is suppressed by short daylengths (Fig. 2*b*). Both the stimulatory and inhibitory centres are removed by the extirpation of the PI. This results in a low baseline reproductive activity for both photoperiods (Fig. 2*c*).

The common belief that the inactivity of the CA and the arrest of reproduction are caused by the diapause-promoting photoperiod only through an absence of the activation hormone

Fig. 2 Hypothetical model of photoperiodic regulation of reproduction in *P. apterus*. *a*, Intact females; *b*, females with nervi allati transected; *c*, females with pars intercerebralis extirpated. cannot thus apply to all insects. In some species at least, reproductive inactivity is assured by a double mechanism—not only by the absence of humoral stimulation but also by the inhibition of the CA through the nerves. Such evidence has been obtained in *P. apterus*[9] and in *Locusta migratoria*[11]. A more detailed description of the present results will be given elsewhere.

TRH potentiates excitatory actions of acetylcholine on cerebral cortical neurones

ANTAGONISM of barbiturate-induced sleeping time in experimental animals[1] is one of the interesting pharmacological properties of thyrotropin-releasing hormone (TRH; pyroglutamyl-histidyl-proline amide) which are independent of its effects on endocrine function. Moreover, this effect of TRH is reduced or inhibited by atropine, suggesting that cholinergic mechanisms contribute to some of the effects of TRH (ref. 1). It can be shown that general anaesthetics (barbiturates in particular) selectively reduce the sensitivity of cerebral cortical neurones to the excitatory actions of iontophoretically applied acetylcholine[2-4]. This anaesthetic interference with cholinergic, muscarinic excitations has been postulated to participate in the regulation of levels of consciousness[5]. In view of these considerations it might be predicted that TRH would alter the effects of acetylcholine (ACh) on cortical neurones and the experiments described below were designed to test this hypothesis. The results indicate that TRH potentiates the excitatory actions of ACh on cortical neurones.

Female rats (200–210 g, Charles River) were anaesthetised with pentobarbital sodium (50 mg kg^{-1}) with supplemental intraperitoneal injections when required. A small burr hole was drilled over the somatosensory cortex and after reflection of the dura the exposed cortex was covered with 0.5% agar to prevent drying. Neuronal activity was recorded by conventional means through the use of multibarrelled glass micropipettes (tip diameter, 5–10 μm), the centre barrel being filled with 2 M NaCl. The outer barrels of the electrodes were filled immediately before use by centrifugation with solutions of acetylcholine chloride (0.2 M), Na glutamate (0.5 M), carbamyl choline chloride (carbachol, 0.2 M), and TRH (0.05 M in 165 mM NaCl). Automatic current balancing through a barrel containing 2 M NaCl was used to reduce current artefacts.

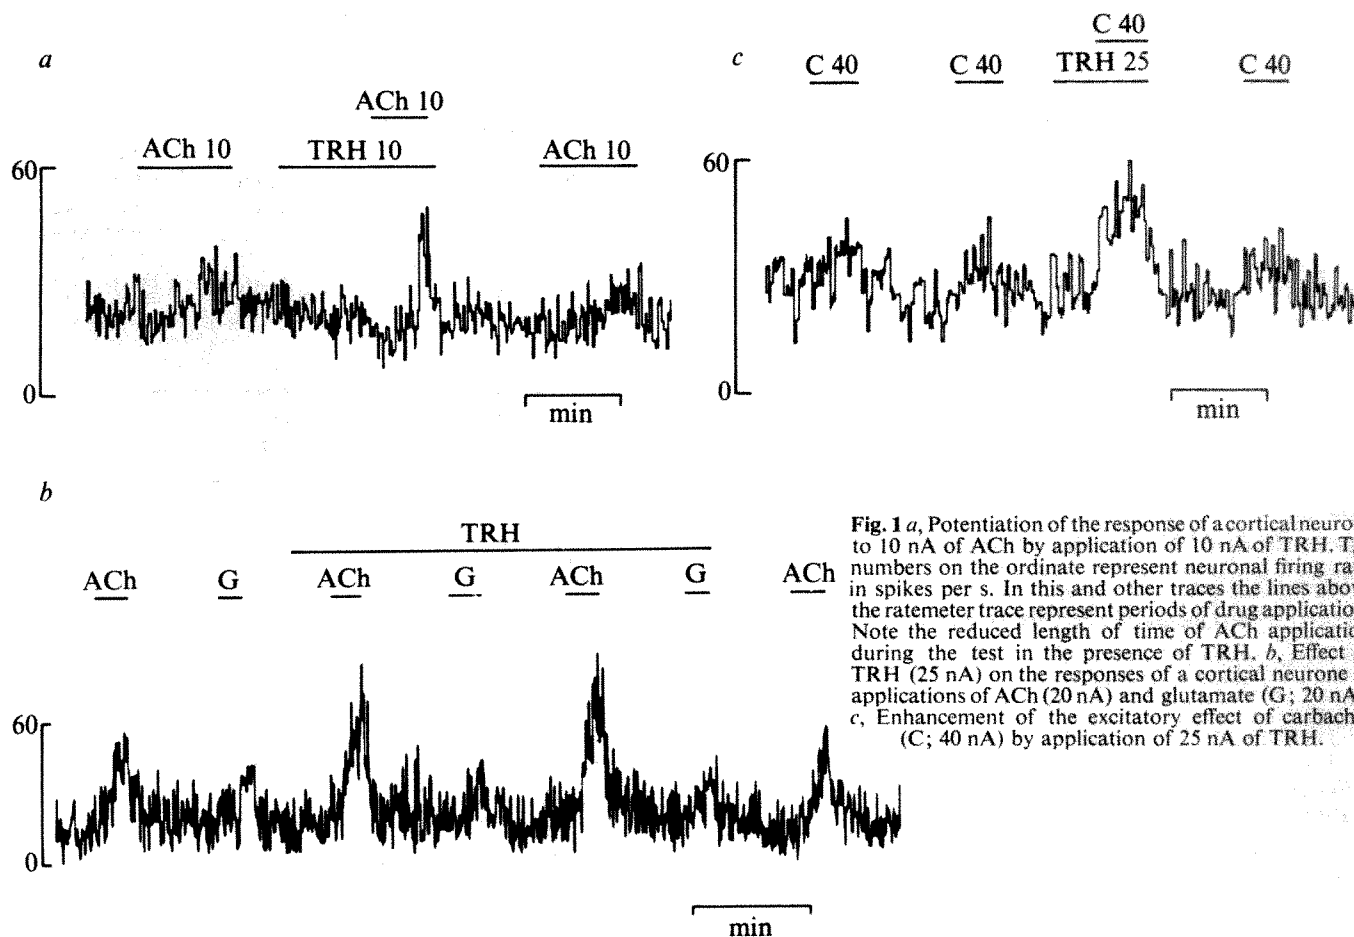
Spontaneously active neurones, located between 750 μm and 1,250 μm from the cortical surface were examined since the muscarinic nature of ACh excitations of cells in this region of the cortex is well documented[6]. Applications of TRH (ejected with anodal current, 10–70 nA, 30 s–4 min) consistently enhanced the action of iontophoretically applied ACh (10–40 nA, 15–60 s). Thus, on 16 of 18 cells tested, TRH either poten-


Fig. 1 *a*, Potentiation of the response of a cortical neurone to 10 nA of ACh by application of 10 nA of TRH. The numbers on the ordinate represent neuronal firing rate in spikes per s. In this and other traces the lines above the ratemeter trace represent periods of drug application. Note the reduced length of time of ACh application during the test in the presence of TRH. *b*, Effect of TRH (25 nA) on the responses of a cortical neurone to applications of ACh (20 nA) and glutamate (G; 20 nA). *c*, Enhancement of the excitatory effect of carbachol (C; 40 nA) by application of 25 nA of TRH.

tiated the excitory actions of regularly applied pulses of ACh or converted an inactive ejection current of ACh to a typical ACh excitation. An example of this phenomenon is illustrated in Fig. 1*a*. TRH itself did not directly alter the excitability of the cells tested, nor did it seem to modify substantially the response of 11 cells tested with 20–50 nA of glutamate. Figure 1*b* shows a cell in which the response to ACh was clearly enhanced during the application of TRH while not obviously affecting the response to repeated, submaximal applications of glutamate. Since a possible explanation for the ability of TRH to enhance ACh excitations while not affecting glutamate responses might be that of acetylcholinesterase inhibition, the interactions of TRH and carbachol (not subject to degradation by acetylcholinesterase) were examined. On 11 of 13 cells tested, TRH potentiated the excitatory actions of carbachol (10–40 nA) and a typical example is shown in Fig. 1*c*. This effect of TRH on excitations produced by both ACh and carbachol was consistently brief in onset (sometimes occurring when the TRH and cholinergic agonist were applied simultaneously) and offset.

TRH and other peptides are being increasingly investigated with regard to their possible roles in neural function. The regional and widespread distribution of TRH throughout the neuroaxis[6,7], coupled with the demonstration of a depressant effect of TRH on neurones in a variety of areas[8,9] within the central nervous system (CNS), indicates that TRH might subserve a transmitter function. TRH was not observed to have any direct effects on neuronal excitability of the restricted population of cells sampled in the present study with the ejection currents used, although it clearly and consistently enhanced the excitatory actions of ACh and carbachol. These findings may provide some insight at the neuronal level for the significant anti-anaesthetic effects of TRH in the light of the above considerations, and furthermore, may provide the basis for new approaches in attempts to understand the functional significance of TRH in the CNS. Thus, although not discounting a possible role of TRH as an intercellular mediator, the hormone may subserve a more indirect function to modulate the actions of certain chemical transmitters.

Incision of ultraviolet-irradiated DNA by extracts of *E. coli* requires three different gene products

IN most organisms pyrimidine dimers induced in DNA by ultraviolet light are removed by excision which is initiated by a repair-specific endonuclease that recognises the damage and makes a strand incision adjacent to the dimer[1–4]. Characterisation of excision-defective mutants of *Escherichia coli* has shown that in this organism early steps of repair are controlled by the *uvrA*, *uvrB* and *uvrC* genes[5]. Although *uvrA* and *uvrB* mutants seem to be incision defective *in vivo*[6,7], it has not been possible to measure any difference in the amount of ultraviolet-endonuclease activity between crude extracts from mutants and wild-type cells[8,9]. After partial purification of wild-type or *uvrC* mutant extracts, however, an ultraviolet endonuclease has

been identified which is absent from *uvrA* and *uvrB* cells[9] (in this communication termed the *uvrAB* endonuclease). The relevance of these results to whole cells is unclear, because recent experiments with permeable cells have shown that *uvrA⁺B⁺*-dependent strand incision requires adenosine-5'-triphosphate (ATP)[10–12], whereas the *uvrAB* endonuclease is independent of ATP[2]. The aim of the present investigation was to observe ATP-dependent ultraviolet-endonuclease activity in a cell-free system. We report here the characterisation in crude extracts of an ATP-dependent ultraviolet-endonuclease activity from *E. coli* and conclude that the activity reflects that the enzyme is essential for repair in whole cells. The activity requires the complementary action of the *uvrA⁺* *uvrB⁺* and *uvrC⁺* products and this has been utilised to establish *in vitro* assays for the individual products of these genes.

In preliminary experiments, extracts made by Brij-58 lysis[13] or lysozyme lysis of freeze-thawed cells[14] were tested for ATP-dependent ultraviolet-endonuclease activity, but results with these extracts were unsatisfactory. Soluble extracts were then prepared by a procedure based on gentle lysozyme lysis of sucrose permeabilised cells (see legend, Fig. 1). This method avoids the use of detergents or freeze-thawing which might affect labile enzyme activities. Typical results obtained by assaying endonuclease activity in extracts from wild-type cells and repair-defective mutants are shown in Fig. 1*a–d*.

In the absence of ATP, extracts from all strains showed similar levels of ultraviolet-endonuclease activity, in agreement with results reported previously[8,9]. Addition of ATP however, caused a fivefold increase in the amount of ultraviolet-endonuclease activity in wild-type extracts, but had only a minor effect on mutant extracts. It is thus clear that the major ultraviolet-endonuclease activity in wild-type extracts requires ATP and depends on functional *uvr* genes. The formation of ultraviolet-induced strand incisions in permeabilised cells has the same characteristics[10,11], and we infer that the activity observed in these extracts reflects the ultraviolet-endonuclease essential for repair in whole cells.

In view of the common deficiency in extracts from cells with mutations mapping at distinct loci, *in vitro* complementation between different mutant extracts was attempted. When extracts from *uvrC* and either *uvrA* or *uvrB* cells were mixed, the ATP-dependent ultraviolet-endonuclease activity was completely recovered (Fig. 1*e–f*). Combined extracts from *uvrA* and *uvrB* cells also displayed activity due to complementation, although usually not to the same extent as combinations including *uvrC* extracts (Fig. 1*g*). Evidently, gene products from *uvrA⁺*, *uvrB⁺* and *uvrC⁺* are required for ATP-dependent

Table 1 Effect of various incubation conditions on the ultraviolet-specific endonucleolytic activity from *uvr⁺* cells

Variation in reaction mixture	Ultraviolet-specific endonuclease activity (%)
Complete reaction mixture	100
−ATP	18
3 mM ATP	115
−KCl	35
3.5 mM Mg²⁺	38
10 mM Mg²⁺	100
20 mM Mg²⁺	75
+25 mM caffeine	10
+10 mM NEM	29

Extracts from cells of strain AB1157 *uvr⁺* were assayed in duplicate for nonspecific and ultraviolet-specific endonucleolytic activity (DNA exposed to 225 J m⁻² of ultraviolet). Net ultraviolet-specific activity was calculated substracting the amount of nicked DNA in non-irradiated samples from the amount of nicked DNA in irradiated samples. The activity obtained in standard assay conditions (Fig. 1) including ATP (1.5 mM) in the reaction mixture was normalised to 100% and the effect of additions (+), omissions (−) or change in concentration of a single component was calculated relative to this value.
Fig. 1 Ultraviolet-specific ATP-dependent endonucleolytic activity in extracts from excision-proficient and deficient strains of *E. coli* K12. Soluble extracts from strains AB1157 *uvr*⁺ (*a*), AB1886 *uvrA* (*b*), AB1885 *uvrB* (*c*) and AB1884 *uvrC* (*d*), were assayed for endonuclease activity in the absence (○) or presence (●) of ATP (1.5 mM), using the "nicking" assay of Braun *et al.*[9] with the modification that covalently closed circular colE1 DNA (molecular weight = 4.2 × 10⁶) was used as substrate. Plasmid DNA, ³H-labelled, was extracted from growing cells of strain SK2001 *thy*⁻ colE1 by means of a sodium dodecyl sulphate (SDS)–NaCl lysis procedure, and the covalently closed circular form was purified by phenol extraction and banding in CsCl–ethidium bromide. Details of the purification procedure will be described elsewhere (Nissen-Meyer and Seeberg, to be published). For extract preparation cells were first treated with high sucrose as described by Hurwitz *et al.*[19] and then lysed with lysozyme. Approximately 10¹⁰ exponentially growing cells were suspended in 0.25 ml 2.5 M sucrose (0.04 M Tris, pH = 8.0, 10 mM EGTA) and the suspension diluted fivefold in a buffer (50 mM MOPS, pH = 7.5, 100 mM KCl, 1 mM EDTA, 1 mM dithiothreitol), containing 125 μg ml⁻¹ of lysozyme. After 45 min on ice, the lysates were centrifuged at 10,000g for 15 min. The supernatant, subsequently referred to as extract, was completely soluble, essentially DNA free (less than 0.1 % of total DNA), and contained approximately 6 mg of protein. Standard reaction mixtures (130 μl) contained 40 mM MOPS, pH = 7.5, 85 mM KCl, 15 mM MgSO₄, 1 mM EDTA, 0.8 mM dithiothreitol, 5 ng DNA exposed to various doses of ultraviolet light (254 nm), and 10 μl extract. Incubation was for 15 min at 37 °C. Incised DNA was selectively denatured and separated from intact DNA by filtration through nitrocellulose as previously described[9]. The fraction of remaining covalently closed circles was determined by scintillation counting and plotted against ultraviolet exposure to the DNA. *e–g*, Results obtained assaying extract mixtures (1:1) of strains AB1886/AB1884 (*e*), AB1885/AB1884 (*f*) and AB1886/AB1885 (*g*). Each value plotted is the average of two or three independent assays and bars indicate standard deviation.

ultraviolet-endonuclease activity and a mutation at any one of these loci does not prevent the formation of functional products from the other *uvr* genes. The complementation provides an *in vitro* assay for the separate *uvrA*⁺, *uvrB*⁺ and *uvrC*⁺ products. The activity of either product can be assayed by *in vitro* complementation with an extract made from the corresponding mutant, measuring ATP-dependent ultraviolet-endonuclease activity. Purification of the *uvrC*⁺ product is now being attempted using this approach. *In vitro* complementation assays have proved very useful in the purification of proteins active in DNA replication[15,16].

The ATP-dependent ultraviolet-endonuclease observed in crude extracts resembles the partially purified *uvrAB* endonuclease described previously, in that both activities are stimulated by moderate concentrations of salt and require the gene products from *uvrA*⁺ and *uvrB*⁺ (Table 1, ref. 9). The activity in extracts requires ATP, fairly high concentrations of Mg²⁺ and the *uvrC*⁺ product (Table 1, Fig. 1). In contrast, the *uvrAB* endonuclease is not stimulated by ATP, acts in the absence of Mg²⁺ and is present in normal amounts and with normal activity in *uvrC* cells[4,9]. These results can be reconciled if the *uvrC*⁺ product interacts with the *uvrAB* endonuclease to yield ATP-dependent ultraviolet-endonuclease activity. The *uvrC*⁺ product may not have a direct role in the production of single-strand breaks, but may possibly be an ATP-requiring factor which promotes the turnover and thereby amplifies the activity of the endonuclease. The activity of the *uvrAB* endonuclease in the absence of the *uvrC*⁺ product may be detectable in extracts from *uvrC* cells where we repeatedly observed slightly more ultraviolet-endonuclease activity than in *uvrA* or *uvrB* extracts (Fig. 1*d*).

Results with *uvrC* cells *in vivo* have suggested that the *uvrC* function may be involved in a step succeeding incision because single-strand breaks slowly accumulate in the DNA of *uvrC* cells during post-irradiation incubation[7,17]. The rate of formation of these breaks seems to be increased by a mutation affecting ligase activity, suggesting that the *uvrC*⁺ product may prevent ligase reversal of the incision reaction and force the subsequent removal of the dimer[18]. Our results do not eliminate this hypothesis, because ligase may be partially active

in the extracts in spite of the absence of the ligase cofactor nicotinamide adenine dinucleotide in the reaction buffer. It seems clear, however, from the results presented in this communication, that the *uvrC*⁺ product in extracts has an essential role in promoting strand incisions, directly or indirectly. Purification of the different components of the ATP-dependent ultraviolet-endonuclease activity seems necessary before the interrelationship between the *uvrA*⁺, *uvrB*⁺ and *uvrC*⁺ products can be defined in detail.

Improved derivative of a phage λ EK2 vector for cloning recombinant DNA

THOMAS *et al.*[1] have constructed a derivative of phage λ (λgt·λC) that is useful for cloning DNA fragments 1,000 to 15,000 base pairs long from other organisms. Their cloning procedure involves cutting the phage DNA into three fragments with *Eco*RI nuclease, removing the central (or "C") fragment, and annealing the outside fragments with an RI digest of foreign DNA. We have recently introduced three amber mutations—*W*am403, *E*am1100, and *S*am100—into λgt·λC with the object of making the phage less likely to encounter a susceptible host in nature[2]. The NIH Advisory Committee on Recombinant DNA Research, on the basis of appropriate tests, has certified λgt*WES*·λC as an EK2 vector[3,4].

In order to extend the usefulness of this vector to the cloning of smaller fragments of DNA (such as synthetic, double-stranded DNA derived from the reverse transcription of mRNA) and to obviate the need for biochemically deleting the 5,400 base pairs central *Eco*RI restriction fragment, λC, we have replaced the λC fragment with the phenotypically inert *Eco*RI fragment λB (refs 5–7).

(In addition to genetic tests necessary to verify the mutations present in λgt*WES*·λC, the right and left restriction fragments of the phage must be purified from the λC fragment before their inclusion in EK2 recombination reactions. The λC fragment encodes genes involved in integration, *int, xis* and *att*, as well as phage-promoted generalised recombination, *red*. This fragment can be accommodated in hybrids with foreign DNA fragments as large as 7,000 base pairs. Thus the λC fragment must be biochemically removed to minimise the opportunity for recombination between bacterial host DNA and a potentially deleterious hybrid as well as to prevent the outgrowth of *red*⁺ reconstituted parent-like recombinant phage. While this purification can be accomplished by sucrose gradient sedimentation or Agarose gel electrophoresis, both procedures are wasteful of time and materials and may damage the single-stranded portion of the RI cleavage site.)

The new derivative retains all the safety features of λgt*WES*·λC but now lacks the λC fragment and the λ elements *int, xis, att* and a portion of the λ *red* gene, which therefore, no longer need to be deleted biochemically. Since the λB fragment contains two immediately adjacent *Sst*I restriction endonuclease sites (S. Goff, personal communication) which enable λgt*WES*·λB to be cleaved into fragments of sufficient length for packaging, it can also be used in conjunction with various "tailing" and "blunt-end ligation" strategies to clone fragments of DNA less than 1,000 base pairs in length. Here we describe the construction and properties of λgt*WES*·λB.

DNA from the two parental phages, λgt*WES*·λC and λgt·λB, were treated with *Eco*RI and permitted to recombine randomly in the presence of T4 DNA ligase (Fig. 1). Plaques obtained after transfection were screened for appropriate markers on three test strains. The desired recombinant contains the left and right arms from the first parent and the λB fragment from the second parent. The presence of amber mutations was recognised by failure to grow on a *sup*O host (*E.c oli* 594), and the presence of *S*am100 by failure to grow on a *sup*E host. The red plaque test was used to detect the absence of the middle λC fragment carrying the *int* and *xis* genes[13]. From candidate recombinants obtained by this screening, the desired phage derivative carrying all three amber mutations was identified by marker rescue studies. Further genetic characterisation has confirmed that this derivative is *red*⁻ and carries *c*Its857 and the *nin*5 deletion (Table 1).

The selected recombinant, λgt *W*am403 *E*am1100 *S*am100·λB, was characterised biochemically by its restriction fragment pattern (Fig. 2). *Eco*RI cleaves λgt*WES*·λB DNA into the three expected fragments: a 21.3 kilobase (kb) left arm, a 13.9 kb right arm and a 4.69 kb middle fragment characteristic of the λB fragment obtained from restriction of λ*c*I857 or λgt·λB DNA. The restriction endonuclease *Sst*I cleaves λ DNA at only two adjacent sites within the λB fragment (S. Goff, personal communication). *Sst*I cleavage of λgt*WES*·λB yields the expected three fragments confirming the presence of the λB fragment. Digestion with *Bam*HI of λgt*WES*·λB and λgt·λB indicates that a single copy of the λB fragment has been inserted in the recombinant in reverse orientation. *Bam*HI cleavage of both phage DNAs yields only four fragments. *Bam*HI would generate a fifth easily-distinguishable band if a second copy of the λB fragment were present, regardless of its orientation with respect to the first. On the basis of their gel mobility, the size of these fragments in λgt·λB are 5.4 kb, 16.7 kb, 6.4 kb, and 11.4 kb as would be expected from the λ *Bam*HI cleavage map[9]. However, in the new recombinant the second and third fragments are 19.3 kb and 3.8 kb, respectively, as would be expected from the fragment orientation shown in Fig. 1.

The new vector, λgt*WES*·λB, greatly simplifies the preparation of hybrid recombinants under EK2 conditions. Since the vector lacks the fragment on which genes for integration and
Fig. 1 Construction of λgt *W*am403 *E*am1100 *S*am100·λB *Eco*RI fragments of the two parents λgt*WES*·λC and λgt·λB are represented as separated solid lines and labelled A, B, C, DEF at the top of the figure. *Bam*HI sites in the phage DNA are represented as arrows and both *Eco*RI (ref. 8) and *Bam*HI (ref. 9) target sites are given at the bottom of the figure as percentage λ unit length. Deletions are represented as hatched boxes. The deletion in the right arm of all three phages is *nin*5. The preparation of λgt *W*am403 *E*am1100 *S*am100·λC DNA has been described previously[2]. The construction of λgt·λB has been described[1]. The phage was prepared from plate stocks[10]. λgt·λB DNA was prepared from purified phage as previously described[2]. λgt*WES*·λC and λgt·λB DNA were digested at 50 μg ml⁻¹, and 25 μg ml⁻¹, respectively, by *Eco*RI at 60 U ml⁻¹ in separate 50-μl reactions containing 0.1 M Tris-HCl, pH 7.9; 50 mM NaCl; 12 mM MgCl₂; 0.1 mM EDTA for 30 min at 37 °C. The reactions were stopped by incubation for 5 min at 70 °C. The DNAs digested with *Eco*RI were then mixed in a 50-μl reaction mixture containing 20 μg ml⁻¹ λgt*WES*·λC DNA, 8.3 μg ml⁻¹ λgt·λB DNA, 0.1 M Tris-HCl, pH 7.5; 50 mM NaCl; 12 mM MgCl₂; 0.1 mM EDTA; 10 mM dithiothreitol; 0.1 mM ATP and 50 μg ml⁻¹ bovine serum albumin and recombined by incubation for 48 h at 9 °C with 0.5 U ml⁻¹ T4 DNA ligase (Miles). The reactions were diluted to 1.0 μg ml⁻¹ DNA and used to transfect a T1-resistant isolate of JC5183 (*E. coli* F⁻ *sbc*A5 *rec*B21 *rec*C22 gal⁻ Endo I⁻) (ref. 11) essentially as described in Cameron *et al.*[12]. The transfected cells were plated with the indicator *gal* deletion strain SA825 (*sup*F). Plaques which contained amber mutations were scored by failure to grow on *sup*O strain 594. Plaques containing *S*am100 were scored by poor growth on the *sup*E strain C600. Plaques containing the λB fragment were scored by their formation of white plaques in the test for *int-xis* devised by Enquist and Weisberg[13]. As indicated in Table 1, candidate recombinants were scored for the presence of *E*am1100 by their growth on *gro*E. The presence of all three ambers was confirmed by marker rescue studies described in Table 1.

Table 1 Genetic analysis of λ vectors

	W*	E*·†	(int–xis)‡	red§	cIts857¶	nin5 ‖	S*
λgt·λC	+	+	+	+	+	+	+
λgt·λB	+	+	−	−	+	+	+
λgt Wam403 Eam1100 Sam100·λC	−	−	+	+	+	+	−
λgt Wam403 Eam1100 Sam100·λB	—	—	—	−	+	+	—

The presence of the genetic marker listed was determined by several methods indicated as follows.
*Complementation tests were performed as described by Shimada *et al.*[14]. +, Plaque formation on 594 (*sup*0); −, no plaques observed for the given complementation test.
†Phage carrying the *Eam*1100 mutation will form plaques (+) on strain Ymel *groE* whereas phage lacking the mutation will not (−) (refs. 2 and 15).
‡The red plaque test for λ *int* and *xis* function was used as described by Enquist and Weisberg[13]. +, Formation of red plaques, thus (*int–xis*)⁺; −, white plaques or (*int–xis*)⁻.
§Phage lacking the λ *red* function will not form plaques on *Feb*⁻ hosts[16]. We used Ymel *lig*ts7 at 32 °C as the *Feb*⁻ host. +, Phage growth on this host; −, no growth.
¶Phages carrying the *c*Its857 mutation form turbid plaques at 32 °C and clear plaques at 42 °C. +, Phages with this phenotype.
‖The presence of the *nin*5 deletion was determined as described in Enquist *et al.*[2]. +, Phages carrying the *nin*5 deletion.

generalised recombination reside, the larger λ fragments need not be purified and the possibility of low-level λC fragment contamination is eliminated. As with λgt*WES*·λC, this vector should accommodate DNA fragments as large as 13–15 kb.

The susceptibility of λgt*WES*·λB DNA to *Sst*I nuclease has
Fig. 2 Restriction enzyme analysis of λgt *W*am403 *Eam*1100 *Sam*100·λB DNA. *a*, λgt *W*am403 *Eam*1100 *Sam*100·λC (*Eco*RI); *b*, λgt *W*am403 *Eam*1100 *Sam*100·λB (*Eco*RI); *c*, λgt·λB (*Eco*RI); *d*, λgt·λB (*Bam*HI); *e*, λgt *W*am403 *Eam*1100 *Sam*100·λB (*Bam*HI); *f*, λgt *W*am403 *Eam*1100 *Sam*100·λB (*Sst*I); *g*, λgt *W*am403 *Eam*1100 *Sam*100·λC (*Sst*I). The mobility of standard λ*c*I857 *Eco*RI fragments in this gel system is represented by the horizontal lines and then sizes are given in kilobase pairs. λgt *W*am403 *Eam*1100 *Sam*100·λB phage was prepared by liquid infection initiated at a multiplicity of 0.01 and a cell density of 2 × 10⁸ ml⁻¹. After an 8-h incubation at 37 °C, the suspension was treated with 1% CHCl₃ for 10 min at 37 °C, brought to 10 mM MgCl₂, and centrifuged for 10 min at 20,000*g* to remove cell debris. λ*c*I857, λgt *W*am403 *Eam*1100 *Sam*100·λC and λgt·λB phage were prepared from induced lysogens or plate stocks[10]. Phage purification and DNA isolation have been previously described[2]. DNA solutions (30 to 830 µg ml⁻¹) are stored at 0–5 °C in 10 mM Tris-HCl, pH 7.5; 0.1 mM EDTA. *Eco*RI was purified from *E. coli* BRY 13.3/1100.5 (to be described elsewhere). Purified *Sst*I was the gift of Dr Steven Goff. *Bam*HI was obtained from Bethesda Research Labs. The standard restriction reaction contained 0.3 µg DNA in 25 µl and sufficient enzyme to cleave 1.0 µg DNA. The *Eco*RI buffer was 0.1 M Tris-HCl, pH 7.9; 50 mM NaCl; 0.1 mM EDTA; 12 mM MgCl₂. The *Sst*I and *Bam*HI buffer was 20 mM Tris-HCl, pH 7.5; 7.0 mM MgCl₂; 60 mM NaCl; 2 mM β-mercaptoethanol. The reactions were incubated for 45 min at 37 °C. After subsequent incubation for 5 min at 75 °C, the reactions were electrophoresed through 1.0% Agarose (SeaKem) slab gels as described previously[17]. The DNA was stained by immersion in 0.0025% ethidium bromide for 3 min and made visible under an ultraviolet lamp. The small 1.0-kb band generated by the *Sst*I cleavage is not readily visible in the contact print of this gel system.

two implications. First, it should be possible to treat the vector with *Sst*I as well as *Eco*RI before hybrid formation to eliminate the bulk of parental recombinants. The *Eco*RI λB fragment when reduced to two fragments each with one *Eco*RI and one *Sst*I end will still anneal to other *Eco*RI-ended fragments but will require the ligation of two *Eco*RI cleavage sites and an *Sst*I cleavage site in order to form a viable transfectant. The introduction of foreign DNA fragments containing only *Eco*RI ends requires only the annealing and ligation of two *Eco*RI sites. Second, the two arms created by *Sst*I cleavage of λgt*WES*·λB DNA are sufficiently longer than the *Eco*RI arms to allow them to be resealed into plaque-forming DNA. *Sst*I arms thus represent a potential EK2 vector for insertion of low molecular weight double-stranded DNA molecules which are too short for insertion into the *Eco*RI arms alone.

We thank Dr R. W. Davis for λgt·λB phage, Dr S. Goff for purified *Sst*I, Dr J. Davies for *E. coli* BRY 13.3/1100.5, Dr A. J. Clark for *E. coli* strain JC5183, and Drs R. Weisberg and N. Sternberg for helpful discussion. We thank Ms Catherine Kunkle for her assistance in preparing this manuscript.

RNA pattern of 'swine' influenza virus isolated from man is similar to those of other swine influenza viruses

In February 1976, during an epidemic of influenza among military recruits at Fort Dix, New Jersey, five virus isolates were obtained which contained haemagglutinin and neuraminidase antigens indistinguishable from those of isolates of swine influenza virus[1]. Subsequent evidence of elevated serum antibody titre against 'swine' influenza virus in hundreds of individuals at Fort Dix[2] prompted the US government to launch a national immunisation programme against 'swine' influenza virus. One current theory suggests that new, pandemic strains of influenza virus result from genetic recombination of human influenza A viruses and strains of virus that are resident in animal populations[3,4]. According to this hypothesis, recombinants may emerge containing genes derived from the animal virus which code for novel surface proteins, and genes derived from the human virus which confer properties of virulence in man. We have demonstrated that the genetic composition of recombinant viruses could be determined by comparison of RNA patterns of recombinant and parent viruses on urea-polyacrylamide gels[5-7]. We have therefore used the same techniques to explore the possibility that the 'swine' virus isolated from recruits at Fort Dix is a recombinant of swine influenza virus from pigs and H3N2 influenza A virus currently prevalent in man.

Figure 1 shows the RNA patterns of three low passage isolates of 'swine' virus obtained from three patients at Fort Dix. All three isolates are identical with respect to the migration of the eight corresponding RNA segments on urea-polyacrylamide gels, confirming previous observations regarding the reproducibility of the RNA patterns in this system.

We compared the RNA pattern of the New Jersey 'swine' virus isolate with those of four influenza viruses isolated from swine and with that of a H3N2 virus isolated from recruits during the same epidemic at Fort Dix in February, 1976. Figure 2 demonstrates the results of one experiment, but it should be noted that at least three different ³²P-labelled RNA preparations were made from each virus and that numerous gels were run to verify the results.

Figure 2 shows that the RNA pattern of the New Jersey 'swine' virus, A/NJ/11/76, isolated from man (lane 2) is virtually identical to that of the swine virus isolate A/swine/Taiwan/1/75 (lane 3), and except for the fifth RNA segment closely resembles the pattern produced by another swine virus isolate, A/swine/Tennessee/1/75 (lane 4). Comparison of a third swine virus, A/swine/Wisconsin/1/73 (lane 7), and the New Jersey 'swine' virus (lane 8) reveals close similarity of the top four RNA segments as well as slight differences in mobility of RNA segments five to eight. In contrast, each of the RNA segments of the H3N2 virus, A/NJ/743/76 isolated from recruits during the same epidemic at Fort Dix (lane 1) could be distinguished from the corresponding RNA segments of the New Jersey 'swine' virus (lane 2), except possibly for RNA segment three. Note that the fourth segment of both viruses codes for haemagglutinin and the fifth segment of A/NJ/743/76 (H3N2) and the sixth of A/NJ/11/76 (HswlN1) code for the respective neuraminidases[7,8]. In particular, swine viruses were characterised by a broad diffuse band at the top in which RNAs 1 and 2 cannot easily be resolved. Furthermore, the eighth RNA segments of all swine viruses migrate faster than the corresponding segments of H3N2 viruses.

Figure 2 also demonstrates the RNA pattern of an H3N2 virus isolated from swine in 1970, A/swine/Taiwan/1/70 (lane 6), which except for RNA segment seven is clearly distinguishable from patterns produced by the other swine virus isolates. This observation is in accord with the previous assumption that this strain, A/swine/Taiwan/1/70, is a virus of man which crossed

species barriers and infected pigs[10]. (Comparison of the RNAs of this virus with those of A/Hong Kong/8/68 virus on other gels reveal very similar patterns.)

Figure 3 is a photograph of another gel demonstrating the RNA patterns of some of the viruses not completely resolved
Fig. 1 Analysis of RNAs of three New Jersey 'swine' influenza virus isolates on a 6 M urea–polyacrylamide gel. RNAs were labelled with ³²P during a one-step growth cycle in MDCK (canine kidney) cells as described previously[4-7]. Electrophoresis on a 6 M urea (2.6%)–polyacrylamide gel was carried out according to previously published procedures[5-7]. Migration was from top to bottom. The RNA segments are numbered 1 to 8. *a*, RNA of influenza A/NJ/11/76 (New Jersey 'swine'; HswlN1) virus; *b*, RNA of influenza A/NJ/8/76 (New Jersey 'swine'; HswlN1) virus; *c*, RNA of influenza A/NJ/9/76 (New Jersey 'swine'; HswlN1) virus. Throughout the manuscript we are using the system of nomenclature recommended by the WHO[9]. According to this system only viruses isolated from swine carry the strain designation swine. The strains isolated from recruits at Fort Dix, which are characterised by swine virus surface antigens, are, however, referred to as New Jersey 'swine' viruses in this report.
Fig. 2 Comparison of the RNA pattern of the New Jersey 'swine' influenza virus with those of A/NJ/743/76 (H3N2) virus and four viruses isolated from pigs. Conditions of electrophoresis on the 6-M urea–polyacrylamide gel are as in Fig. 1. The RNA segments of A/NJ/743/76 and the New Jersey 'swine' virus (A/NJ/11/76) are numbered 1 to 8. The haemagglutinin genes (RNA 4) and the neuraminidase genes (RNA 5 or 6) of these two viruses are identified by arrows[7,8]. Lanes: 1, RNA of influenza A/NJ/743/76 (H3N2) virus; 2, 5 and 8, RNA of A/NJ/11/76 (New Jersey 'swine'; Hsw1N1) virus; 3, RNA of influenza A/swine/Taiwan/1/75 (Hsw1N1) virus; 4, RNA of influenza A/swine/Tennessee/1/75 (Hsw1N1) virus; 6, RNA of influenza A/swine/Taiwan/1/70 (H3N2) virus; 7, RNA of influenza A/swine/Wisconsin/1/73 (Hsw1N1) virus; note that in the conditions of labelling and growth used, virus with equimolar distribution of RNAs is not always obtained.

in Fig. 2. (We found it difficult to obtain clear resolution of each sample when many viruses are compared on a single gel.) Again it can be seen that the pattern of the New Jersey 'swine' virus in lane 2 resembles that of A/swine/Wisconsin/1/73 (lane 3) and can be distinguished from that produced by either the 1976 H3N2 strain, A/NJ/743/76, (lane 1) or the H3N2 strain, A/swine/Taiwan/1/70, isolated from swine in 1970 (lane 4).

Based on this preliminary analysis, we suggest that the New Jersey 'swine' strain is closely related to other swine viruses—particularly the A/swine/Taiwan/1/75 virus—with respect to all of its 8 genes and most likely was not derived by recombination involving the current human H3N2 strain.

We recognise potential pitfalls in this kind of RNA analysis. First, slight differences in migration rates of comparable RNA segments of two viruses may reflect only minor differences in nucleotide sequences, masking genetic homology. Second, it is possible that the New Jersey 'swine' virus isolate is a recombinant which derives some of its genes from an unrecognised H3N2 parent. Although we have compared the RNAs of five different H3N2 strains with that of the New Jersey 'swine' virus we are aware that these represent only a small sample of potential parents. In addition, we cannot exclude the fact that some small differences in RNAs may not be detectable by this method. Consequently a definitive analysis of the genetic composition
Fig. 3 Analysis of the RNAs of the New Jersey 'swine' influenza virus with those of A/NJ/743/76 (H3N2) virus and two isolates from pigs. Conditions of electrophoresis are as in Fig. 2 but new RNA preparations were used. The RNA segments of A/NJ/743/76 and the New Jersey 'swine' virus (A/NJ/11/76) are numbered 1 to 8. Arrows identify the haemagglutinin genes (RNA 4) and the neuraminidase genes (RNA 5 or 6)[7,8]. Lanes: 1, RNA of influenza A/NJ/743/76 (H3N2) virus; 2, RNA of influenza A/NJ/11/76 (New Jersey 'swine'; Hsw1N1) virus; 3, RNA of influenza A/swine/Wisconsin/1/73 (Hsw1N1) virus; 4, RNA of influenza A/swine/Taiwan/1/70 (Hsw1N1) virus.

of the New Jersey 'swine' virus can only be obtained by more sensitive and elaborate techniques such as oligonucleotide fingerprinting of all of the RNAs or peptide mapping of each of the gene products.

It is conceivable that the New Jersey 'swine' virus acquired properties of virulence in man after selection during sequential passage in man; but if recombination between human and animal strains is generally required for the emergence of new strains virulent for man, we would regard the New Jersey 'swine' virus to be an unlikely candidate for the next influenza pandemic. (Since the submission of this manuscript it has been reported that the New Jersey 'swine' virus is in fact less virulent for man than other human influenza virus isolates[11].)

We thank Ms Marlene Lin and Ms Kaye Leitzinger for technical assistance, and Drs W. R. Dowdle, B. Easterday, M. Goldfield and R. G. Webster for viruses. This work was supported by the NIH and the NSF.

matters arising

Bicuculline and visual responses

DUFFY *et al.*[1] proposed that the influence of intravenously administered bicuculline on the receptive field properties of neurones in the visual cortices of cats which have experienced monocular deprivation indicates the "active inhibition of the relatively intact input from the amblyopic eye" by information arising from the normal eye.

In investigations of this type, it hardly seems necessary to expose unanaesthetised, paralysed animals (admittedly locally anaesthetised "to avoid possible confounding" of the results) to bicuculline administered systemically, particularly when its action "was often complicated by its potent convulsive effects" The microelectrophoretic administration of bicuculline or other GABA antagonists near physiologically identified neurones in various regions of the visual system would be likely to provide more definitive evidence regarding the involvement and localisation of GABA-mediated inhibitory mechanisms in binocular vision, and their perturbation as a consequence of monocular deprivation, with considerably less distress to the experimental animal.

1 Duffy, F H , Snodgrass, S R., Burchfiel, J L , and Conway, J. L , *Nature*, 260, 256–257 (1976)

DUFFY ET AL REPLY—Curtis has raised[1] at least two issues. He seems to imply that the use of locally anaesthetised animals is improper or unwarranted and, second, he raises the issue of the proper place of iontophoresis in pharmacological studies of the amblyopic animal.

We feel that experimenters have an obligation to minimise an animal's discomfort. No procedure, however, can successfully claim total freedom from trauma. General anaesthesia is probably the best in this regard and should be used whenever possible. General anaesthetics do act on the brain and, in our experience, modify the receptive field characteristics in the visual and somatosensory system. Furthermore,

anaesthetic agents may interact with other experimentally administered drugs, thereby confounding experimental findings and possibly requiring additional experimentation. Since most neurophysiological and neuropharmacological investigations result in an animal's death, we feel that experimenters have an equal obligation to minimise the number of animals used.

In the course of behavioural studies of amblyopic cats, we have administered bicuculline to a number of awake and unrestrained animals. Bicuculline seems to have a sedative effect at low and medium dosage levels. At higher levels, epileptic activity in the EEG and convulsions occur quite suddenly and result in an immediate loss of consciousness Cats do not seem unduly distressed at any time For all these considerations, we felt that the locally anaesthetised preparation was best for our initial experimentation.

We agree with Curtis that iontophoresis is especially useful for discerning the location of a given drug effect within the nervous system, but feel that it has some problems as an exploratory technique. For example, a negative iontophoretic study with bicuculline in amblyopic cats would not have great meaning unless many regions were sampled which would necessitate the use of more animals. We would also point out that when the data obtained with iontophoretic and intravenous drug administration are in apparent conflict, it is by no means certain that the iontophoretic data give a correct perspective. For example, we cite the recent work of Ben-Ari and Kelly[2] where iontophoretic, but not intravenous, flupenthixol blocked the response to iontophoretically applied dopamine. We do plan to make use of iontophoresis in the future and expect that it will be useful in elucidating the detailed mechanism of effect.

Finally we agree that intravenous bicuculline is a toxic agent and have been seeking a safer agent with a longer duration of action. We believe that intravenous administration of ammonium salts may meet these requirements.

Mammalian cell growth regulation

HOLLEY has proposed that mammalian cell growth regulation in culture is regulated primarily by the depletion of diffusable resources, especially polypeptide factors; that the responsiveness of cells to such factors is density dependent; and that this responsiveness changes in a characteristic manner following transformation.

If this theory is correct, the following must be true: (1) that normal and malignant cells differ demonstrably in their growth regulatory policies; (2) that growth control involves a conventional density dependence; (3) that growth inhibition at high density is not merely the result of culture starvation by careless investigators; and (4) that mechanisms other than diffusable substances contribute little to growth regulation.

It may fairly be stated that there is no *in vitro* cell characteristic which has ever been rigorously demonstrated to correlate with and be diagnostic of the malignant state for a broad spectrum of cell types. The following *in vitro* indices are not broad spectrum malignancy correlates: saturation density, multilayering, contact growth inhibition, growth rate, and growth in low serum[1-10]; cell adhesiveness and surface charge[11-14]; lectin agglutinability[15-18]; fibrinolytic activity[19,20]; cell morphology and karyotype[8,9,21,22]. A recalculation of chi-square values for the data of ref. 23, assuming 3T3 cells to be malignant because of their production of tumour angiogenesis factor[24] and *in vivo* tumorigenicity[8], casts grave doubt on the lack of anchorage dependence as a valid tumorigenicity index. Similarly, the status of the LETS-SF complex is in doubt because many studies of it have used as "normal" controls either cell lines of untested tumorigenicity or lines known (3T3 (ref. 2), BHK21 (refs 9 and 25) or suspected (Wi38 ref. 24)) to be tumorigenic. Holley's argument about growth policy differences between normal and malignant cells is clearly without foundation.

Holley contends that density-dependent growth regulation is "due to a quantitative increase in the requirements for macromolecular growth factors as cell density increases." His only basis for this statement is the citation of three references which speculate about growth regulation by the density-dependent

control of cell surface area and nutrient uptake, a theory which now seems unlikely[34,35], and "wound healing" in monolayer culture. This wound healing, once thought to be density dependent, now seems to involve the destruction of an external diffusion barrier near the cell surface[36]. In certain culture systems, growth inhibition definitely does not involve density dependence[27].

Holley defines density-dependent growth regulation as a tendency for cells "to grow to a 'saturation' density and then stop growing." This definition is unsatisfactory. Density dependence is a change per cell in the value of a cellular property as population density changes. As a rule, a density dependence of growth operates at all population densities and may involve either or both the promotion and inhibition of growth rate[10,26,27]. In culture, the inhibition of cell growth usually occurs even when nutrients and diffusable factors are in excess and not rate limiting[3-5,10,27-33]. Although in well fed cultures growth inhibition is occasionally observed[4], it occurs at much higher densities than are normally employed and probably reflects the restriction of diffusional transport either by an external diffusion barrier[36] or by multilayering. Growth inhibition and its density dependence in culture are not usually the result of resource depletion except for the special situation in which the investigator fails to provide adequate nutrient to his cultures. In general, both 'saturation' density and quiescence are starvation artefacts[3-6,10,27-33].

Holley's acceptance of the physiological significance of certain diffusable growth affectors is uncritical. Of the materials he cites, only the nerve and epidermal growth factors (NGF, EGF) are clearly growth regulators *in vivo*. Plant lectins certainly are not, cyclic AMP probably is not[37-40], while the role of fibroblast growth factor, insulin, hydrocortisone, prostaglandins, antigens, and proteolytic enzymes *in vivo* is unknown. Since blood vessels are selectively permeable, the mere presence of a growth affector in serum does not mean that the substance regulates cell growth. Its presence in the interstitial fluid surrounding a suspected target cell must also be demonstrated. Similarly, a growth affector from one species of vertebrate cannot be considered physiological when applied to cells from another, as is the case with several of the studies Holley cites. Even Holley's use of the term 'polypeptide factors' is in error. Such factors (S₂, erythropoietin, EGF, NGF, S₁) are often multimers and often of very high molecular weight (26, 46, 74, 140, 600 kdalton respectively); or very small and not polypeptides at all (putrescine, uridine, adenine).

Finally, recent evidence raises the possibility that the extracellular matrix

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

---

may contribute to growth regulation in some systems[41-43], and that contact interactions may also[27], though not in the manner postulated by Todaro and others.

In summary, growth regulation is complex, confusing, and not at all understood. Certain diffusable substances (NGF, EGF, erythropoietin, colony-stimulating activity) are clearly physiological growth regulators. And certainly density-dependent growth regulation occurs in many culture systems, though it is far more complex and often differs fundamentally from Holley's description of it. While density-dependent growth regulation is sometimes mediated by diffusable substances, it is probably at times mediated by matrix and contact interactions as well. There is at present no evidence for density-dependent increases by cells in their resource requirements, nor is there evidence that resource depletion regulates growth *in vivo*. Even in culture, resource depletion seldom contributes to growth regulation of well fed cells. Finally, no general difference between normal and malignant cell growth regulation in culture has ever been rigorously proved.

HOLLEY REPLIES—Growth regulation is complex, but I believe Skehan makes the subject unnecessarily confusing.

It is unlikely that all tumors are identical, so it is unrealistic to expect the absolute correlation of tumorigenicity with a single property as Skehan demands[1]. Nevertheless, there are differences between "normal" and tumorigenic cells and the two types of cells often differ greatly in their growth behaviour in cell culture. It is important to understand the differences that are observed and this was the subject of the review[2].

Skehan is influenced by what he considers to be a discovery of "growth inhibition" at low cell density[3]. In my view, Skehan has not discovered a growth inhibition but rather uses the term incorrectly, and has confused the literature. Cell cultures that begin with quiescent cells normally show a lag period, then a period in which there is one relatively synchronous cell division, and then an extended period of asynchronous growth. Skehan plots[3] such a growth curve in the form of growth rate per day and concludes that there is "growth inhibition" at the end of the period of synchronous cell division, since the rate of appearance of new cells falls. In my view, the transition from a brief period of synchronous cell division to asynchrony in a growing population is not properly called "growth inhibition."

There are several inaccuracies in Skehan's present comments[1] but they will be detected by anyone who reads the review[2].

reviews

Credentials of astro-archeology

A. J. Meadows

Megaliths, Myths and Men: An Introduction to Astro-Archaeology. By Peter Lancaster-Brown. Pp. 324. (Blandford: Poole, Dorset, 1976.) £4.75.

Is there such a subject as astro-archaeology? The word obviously implies not only that pre-literate cultures possessed an astronomical tradition, but also that some part of the tradition can be retrieved from surviving artefacts. The most frequently cited instance of such retrieval—and the one that forms the theme of this book—is provided by the megaliths and their alleged orientation towards astronomically significant points on the horizon. The problem is the degree of certainty that can be attached to any conclusions—after all, some of the proposed orientations, with their accompanying interpretations, are still in dispute today after nearly a century of discussion.

A central difficulty is that we are not dealing with a single debate, but with a range of topics not all of which are contested with equal vigour. At one extreme, there is the basic question —Do any astronomically significant orientations of megaliths indisputably exist? Then, somewhere in the middle, one might ask whether astronomically sophisticated orientations—for example, to particular bright stars—occur. At the other end of the spectrum, can any significance at all be attached to the so-called 'leys'—that is, alleged alignments of widely differing prehistoric features, often over considerable distances?

Mr Lancaster-Brown's book, which examines all these questions, is intended for the uninitiated. Technical astronomy is not avoided, but the necessary concepts and jargon are introduced as the need arises. A genuine beginner may find the problems of the celestial sphere occasionally hard to visualise, but the explanations are generally clear. The text is primarily concerned with present-day attitudes, but we are also given an extended survey of the historical development of interest in the subject. These two themes are by no means distinct, for part of the continuing controversy over the credentials of astro-archaeology has derived from the excessive claims of some of its past adherents. A short diversion outside

Western Europe to examine pyramidology ties in both with the main discussion of astronomically oriented monuments, and with a subsidiary question that has often been raised simultaneously: whether or not the builders of megalithic structures used a standard measure of length.

In terms of our initial range of topics, as Mr Lancaster-Brown notes, the majority of people who have examined megaliths now believe that astronomical orientation of some sort is certainly present. At the other extreme, few—except occultists—give much credence to leys. But the uncertain area remains the exact level of astronomical sophistication enshrined in the megaliths. Quite clearly, opinion in recent years has tended to allow our distant ancestors a more detailed aquaintance with astronomy than hitherto. This change has been partly

caused by the accumulation of data from new and more detailed surveys: but partly it stems from a somewhat greater willingness on the part of archaeologists to accept that our ancestors were actually capable of such sophistication. It is unfortunate in this respect that so much space in the book is devoted to Stonehenge, since, although it may be fascinating from the point of view of speculative astronomy, it is one of the astronomically over-explained monuments in the eyes of archaeologists. Again, archaeologists might wish to quibble at one or two omissions from the list of select references. But the book adequately fulfills its role as an introductory survey. □

Professor Meadows is Head of the Department of Astronomy and History of Science at the University of Leicester, UK.

Soil science and archeology

Soil Science and Archaeology. By Susan Limbrey. Pp. 384. (Academic: London.) £8.40.

IN recent years there has been a marked increase in the application of science to archaeology, but soil science has tended to be under-emphasised; this book corrects such a deficiency. The first part of the book summarises the nature of soil properties and pedogenesis. These principles are demonstrated in the following two parts by the description and evolutionary analysis of soils from selected environments. In the fourth part attention is focused on the archaeological attributes of soils.

The inevitable problem with a book of this title is defining the audience to whom it is addressed; it could have been written as a research text for soil scientists involved with archaeology or as an introductory text on soils relevant to field archaeologists. Instead it is written for archaeologists at all levels, but many will find the first part hard going, since a firm scientific background is assumed. Indeed the first three parts will prove to be of great use to students of soil science *per se;* in

particular, the chapters on the history of podzolised and chalk soils in Britain are scholarly articles in their own right.

The only general criticism which can be made is that the reader will not gain detailed advice on how to carry out various procedures—for example, the classification and mapping of soils. A common request to a soil scientist on an archaeological project is a soil or terrain map, and the fieldwork has usually to be completed within a short field season. A demonstration of the necessary techniques could have centred around the greater use of examples and illustrations.

But Dr Limbrey has produced an authoritative text which deserves a wider audience than its title might imply. The usefulness of soil science to archaeology is very well demonstrated, and the potential contribution of archaeology to our understanding of soil evolution is equally stressed.

Donald A. Davidson

Donald Davidson is a lecturer in the Department of Geography at the University of Strathclyde, UK.

Enzyme electrophoresis

Handbook of Enzyme Electrophoresis in Human Genetics. By Harry Harris and D. A. Hopkinson. (North-Holland : Amsterdam, 1976.)

RECOGNITION that enzymes may occur in multiple, electrophoretically distinct, forms first found important practical applications in clinical laboratories where attention has been concentrated on the relatively few isoenzymes known to be of diagnostic significance. The discovery of isoenzymes, however, has had an even greater impact in genetics. Enzyme heterogeneity has been studied by electrophoretic and other techniques at the MRC Human Biochemical Genetics Unit for about two decades. The authors have now provided a distillate of their vast experience in this handbook which is supplied as loose leaves in a ring binder to which supplements can be added as they become available.

After briefly outlining the significance of isoenzymes, the principles of enzyme electrophoresis and methods for their subsequent detection, techniques for the more important methods, especially starch-gel edectrophoresis, are described in sufficient detail to enable them to be set up elsewhere. The main part of the work is devoted to individual enzymes with summaries of necessary technical modifications and examples of the patterns obtained. Finally, brief tabulated sections deal with enzyme subunits and the effects of thiol reagents, together with useful appendices.

As would be expected from such distinguished authors, the work is authoritative and well written. The methods are clearly and concisely presented and, although no attempt is made to give a complete bibliography, sufficient key references are included to enable original sources to be traced. Minor criticisms concern the use of certain obsolescent terminology—for example, glutamate–oxaloacetate transaminase—and the lack of standardisation of the abbreviations. These, however, are trivial matters which do not detract from the value of the book. It will be useful, not only to geneticists, but also to clinical biochemists who at any time may encounter hitherto unsuspected enzyme anomalies.

J. H. Wilkinson

J. H. Wilkinson is Professor of Chemical Pathology at Charing Cross Hospital Medical School, University of London, UK.

Subnuclear components

Subnuclear Components: Preparation and Fractionation. Edited by G. D. Birnie. Pp. 334. (Butterworth: London and Boston, Massachusetts, March 1976.) £15.

Subnuclear Components is a valuable book for the practising research worker. It explains the immediate reasoning behind some popular preparative techniques in an area in which the end justified the means. Happily, assessment of the end-product is included in most of the chapters. The discussions all lie in the areas between detailed descriptions of techniques and expositions of general principles, and provide a very valuable insight into the thinking and background associated with some important experimental procedures. Each of the eight chapters is written by a different author or group of authors, all of whom are busy research workers themselves; and it is not surprising therefore that the text and proof reading are not as polished as I would

otherwise expect for £15 per copy. Less excusable is the long gap between writing and publication, during which time some material has been left behind by events such as the nucleosome model for chromatin; and quite crazy is the tiny print used for the figure captions. Although many of the main techniques have been covered there are gaps in such areas as ribonucleoprotein particles, mitotic apparatus and DNA fractionation (DNA preparation is well covered in a chapter by Dr Butterworth). In the best chapters the available methods are critically discussed and a few chosen for detailed analysis. There are, however, some important gaps—for example, in the otherwise excellent discussion of histone preparation, chromatographic methods are almost ignored. Such problems are inevitable when the authors are presenting the detailed 'behind-the-scenes' analysis which make *Subnuclear Components* so valuable. **Harry R. Matthews**

Harry R. Matthews is a senior lecturer in the Department of Physics at the Portsmouth Polytechnic, UK

Protoplasmic connections in plants

Intercellular Communication in Plants : Studies on Plasmodesmata. Edited by B. E. S. Gunning and A. W. Robards. Pp. xvi + 387. (Springer : Berlin and New York, 1976.) DM72; $29.60.

THIS volume contains 14 review papers presented and discussed at a meeting held in Canberra in June 1975. The aim of the volume according to the editors is to summarise what is known about the nature of plasmodesmata and assess the significance of these intercellular protoplasmic connections in plant physiology. The contributors have performed a valuable service in collecting together information which was previously scattered widely in the literature, and the editors are to be congratulated on the skill with which they have integrated the papers and summarised the discussions at what must have been a very lively meeting.

It is now nearly 100 years since Tangl described strands of protoplasm traversing the cell walls in the endosperm of certain seeds, but because of their extreme fineness (30–60 nm) their very existence remained in some doubt until the advent of the electron microscope. As Robards points out in this volume, in spite of intensive study in the past 10 years, many of the details of struc-

ture remain unresolved. In particular the relationship between the desmotubule and the endoplasmic reticulum of the adjoining cells is still uncertain.

Even greater controversy surrounds the operation of plasmodesmata and much of the volume is devoted to this problem. The early suggestions of Haberlandt that protoplasmic connections may function both in the translocation of substances and transmission of stimuli are supported by a wealth of more recent circumstantial evidence, but an unequivocal demonstration that things actually move through plasmodesmata is still awaited. Tyree has established that plasmodesmata may have sufficient capacity to transport solutes at the fluxes observed, but the basis of such transport is still obscure. This volume, with its extensive bibliography, will form an excellent springboard for anyone wishing to advance our knowledge in an intriguing field of research.

The book is printed from 'camera-ready' typescripts without justified margins and one might have expected that the saving in time and cost would be reflected in more rapid publication and lower price than has been achieved. **James F. Sutcliffe**

James Sutcliffe is Professor of Plant Physiology in the School of Biological Sciences at the University of Sussex, UK, and Editor-in-Chief of Annals of Botany.

obituary

John Richardson Marrack, DSO, MC, Emeritus Professor of Chemical Pathology in the University of London, died in the USA on June 13, 1976. He was born on November 26, 1886 at Clevedon, Somerset, but soon moved to Tiverton, where he attended Blundell's School, to which he remained greatly attached, and of whose Old Boy's association he later became Vice-President. He went to St John's College, Cambridge and then to the London Hospital Medical College, graduating in 1908.

His first research was on rheumatoid arthritis as a John Lucas Walker student, and later Beit Memorial Fellow at the laboratories of the Cambridge Research Hospital (which has become the Strangeways Laboratory). After the First World War, when he served in the RAMC, he went to the London Hospital as lecturer in Chemical Pathology. He became interested in the properties of colloids, initially from studying the binding of calcium by serum proteins, and came to the conclusion that colloid interactions were caused by definable and verifiable physical and chemical forces, acting between distinct protein entities. As an example he chose antibodies, whose nature was quite unknown and whose very existence as separate entities was doubted. In 1930 he showed that diphtheria antitoxin behaved as a distinct protein whose interaction with diphtheria toxin could be measured quantitatively. In a monograph published in 1934 (*The Chemistry of Antigens and Antibodies*) he proposed that the specific affinity of antibodies for antigens is determined by the same factors which determine the specific binding of molecules to form crystals, that is, the shape of the molecules and the spatial distribution and strength of

polar forces. The monograph contains a clear diagram elaborating the theoretical studies of Heidelberger and Kendall to illustrate what has now become accepted as the 'lattice hypothesis' of antigen–antibody interactions.

Revised in 1938 this work has had a lasting influence, and convinced many chemists and biochemists that immunology was a fit subject for scientific study by themselves as well as by bacteriologists and serologists. Marrack was also the first to use methods which are now commonplace: equilibrium dialysis, whereby he indicated that anti-hapten antibodies were probably bivalent, and the attachment of coloured dyes to antibacterial antibodies, which inspired Albert Coons later to develop the technique of immunofluorescence. Marrack wrote few papers, by present day standards, and his encyclopaedic knowledge of immunochemistry appeared mostly in review articles.

John Marrack was a colourful character. Behind a shyness and apparent abruptness lay kindness and intellectual integrity. He always wanted to be an athlete and was by temperament a fighter—for seven years he was welterweight champion in the London University boxing tournaments. Throughout the whole of his adult life he was a keen walker (he knew Dartmoor intimately) and he never drove where he could go by bicycle. On more than one occasion when roused to righteous anger he took the law into his own hands and used his fists: once to apprehend a thief in the laboratory and again to despatch a gang of hoodlums who misguidedly attacked him on Whitechapel Station. His war record in the RAMC—DSO as a line medical officer and MC for investigations on the poison gas used

against the British Army in 1917—illustrates this aspect of his character. So also does his consistent championship of the underdog.

During the Civil War in Spain, he was an active member of the Spanish Medical Aid Committee, and visited the International Brigade and the Spanish Republican army. About this time he became deeply concerned about the nutrition of children in Britain, influenced by L. J. Harris and Jack Drummond, and spent much time and effort campaigning for the Children's Nutrition Council—to such good effect that he was adviser to the Ministry of Food during the Second World War and wrote in 1942 a book (*Food and Planning*) which influenced the post-war planning of nutrition.

These activities were regarded by many of his contemporaries as indicating that he was finished with research, but were entirely consistent with his character. When he returned to the laboratory in the Department of Pathology at Cambridge in 1952, his main work had, in fact, been completed, but he began to exploit the growing knowledge of the structure of antibodies while devoting most of his energy to editing, for its first ten years, virtually single handed, the new journal *Immunology*. By now the importance of his earlier work had become widely understood and recognised and at the age of 76 he was made Visiting Professor at the University of Texas. At the First International Congress of Immunology in 1971 he was one of five to receive the Distinguished Service Award "For revolutionary ideas that have become commonplace in his lifetime, and for pioneering work in the physicochemical interpretation of antigen–antibody interactions".

J. H. Humphrey

Marie Laura Violet Gayler, March 1891–August 1976, was the youngest of five daughters of Mr William Gayler, Director of Stamps and Excise at Somerset House. Her mother was an artist, a Gold Medallist of the Slade School, whose paintings were often exhibited at the Royal Academy. Marie graduated from London University in 1912, and after teaching botany at the Colstan Girls' School, Bristol, in 1915 she joined Walter Rosenhain's scientific staff in the Metallurgy Department of the National Physical Laboratory, and later married Dr J. L.

Haughton, a member of the same Department. She retired in 1947.

Marie Gayler and a physical chemist, Miss I. H. Hadfield, were the first women to be appointed to the scientific staff of the Department. She became a distinguished member of Rosenhain's team, which in the 1920s and 30s at the NPL, helped to lay the scientific foundations of physical metallurgy and to give this country the leading position which it enjoyed in the subject for a couple of decades or more.

Marie Gayler's outstanding contribution, with Hanson and Haughton,

was the elucidation of the mechanism of age-hardening in the duralumin family of aluminium alloys, which had been developed empirically by Wilm in Germany. A very important outcome of the NPL work was Y-alloy, an aluminium alloy which contained nickel as well as copper, magnesium and silicon, the normal alloying elements in duralumin. The presence of nickel greatly improves the strength and hardness of age-hardened duralumin at temperatures of 150–200 °C. This makes Y-alloy eminently suitable as a material for the pistons of internal

combustion engines. Many derivatives of Y-alloy have been developed, among which are the RR series of alloys, one of which is used in the skin of the Concorde which is heated by passage through the air at supersonic speeds.

In the 1930s and 40s Marie Gayler took over the work at the NPL on dental amalgams. To understand the mechanism of the setting and hardening of amalgams she followed the traditional NPL procedure, which was to establish the metallurgical constitution of the alloys, consisting essentially of silver, tin and mercury. The setting proceeds by diffusion at room temperature of the mercury into the powdered silver-tin alloy. Novel metallographic techniques had to be worked out for the study of the complex processes of diffusion and reaction. To ensure the satisfactory prosthetic performance of the amalgam filling, close control of the volume changes occurring during and after setting must be assured. In recognition of this side of her work Marie Gayler was made an Honorary Member of the British Dental Association in 1947.

Although her principal researches were concerned with aluminium alloys and dental amalgams, Marie Gayler also carried out important investigations on iron-manganese alloys, and on the melting points of pure silicon and iron. In 1947 the Institute of Metals, in whose Journal many of Marie Gayler's papers were published, awarded its Platinum Medal jointly to her and her husband, Dr J. L. Haughton.

After her retirement she was able to devote more time to her interest in sculpture; she sculpted the head of the late Professor Hume-Rothery; which now stands in the library of the Department of Metallurgy in Oxford University.

Marie Gayler readily absorbed and whole-heartedly transmitted Rosenhain's enthusiasm and scientific resourcefulness. She worthily maintained and enhanced the traditions of the Metallurgy Department of the NPL, and her surviving colleagues remember her as a warm and helpful colleague of striking and attractive appearance.

A. J. Murphy

announcements

Meetings

November 11, **Ecdysone Workshop,** London (Dr. D. L. Whitehead, Tsetse Research Laboratory, Department of Veterinary Medicine, Langford House, Langford, Bristol BS18 7DU, UK).

January 29–30, 1977, **Human Skin Banking,** Milwaukee, Wisconsin (Ralph M. Guttman, MS, Director, St Mary's Skin Bank, PO Box 503, Milwaukee, Wisconsin 53201).

March 2–4, 1977, **Cell Differentiation and Neoplasia,** Houston (Stephen C. Stuyck, MD, Anderson Hospital and Tumor Institute, Houston, Texas 77030).

March 28–April 1, 1977, **Scanning Electron Microscopy,** Chicago (Deadline for abstracts: October 25) (Om Johari, Annual SEM Symposia, IIT Research Institute, 10 W 35th Street, Chicago, Illinois 60616).

May 3, 1977, **Crop Protection,** Ghent (Prof. Ir. R. H. Kips, Chairman of the Organising Committee, International Symposium on Crop Protection, Faculteit van de Landbouwwetenschappen, Coupure Links 533, B-9000 Ghent, Belgium).

May 17–21, 1977, **Study of Macromolecules by NMR,** Grasmere, UK (Dr D. H. Richards, Explosives Research and Development Est., Non-metallic Materials Branch, Powdermill Lane, Waltham Abbey, Essex).

July 11–14, 1977, **Gas Kinetics,** Manchester (Fifth International Symposium on Gas Kinetics, UMIST, PO Box 88, Manchester M60 1QD).

July 11–15, 1977, **Organometallic and Co-ordination Compounds of Ger-**

Person to Person

A limited number of copies of the *Genetic Hazards to Man from Environmental Agents,* the proceedings of a symposium held in Ottawa in May, 1975, and published in *Mutat. Res.,* **33,** (1), (1975) are available to scientists who would not have access to it otherwise. Please write to Dr John A. Heedle, Department of Biology, York University, 4700 Keele Street, Downsview, Ontario M3J 1P3, Canada.

I am conducting experiments on the variations of fungal pathogens of rice induced by pesticides. Those who are working on similar topics may please contact me if interested in exchanging views on this subject (Dr S. Balakrishnan, Dept of Pathology, College of Agriculture, Vellayani PO, Trivandrum, Kerala, India).

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

More than facts, judgments

THE idea of a Science Court has gained a modest amount of momentum in the United States (*Science*, August 20, p 653; *Nature*, October 7, p 454). It would concern itself solely with providing "factual statements of the highest presumptive validity consistent with time constraints". For this, an adversary procedure would be used and a panel of judges with skills in adjacent areas would be expected to examine statements and, if necessary, write their own opinions on contested matters. Issues which might come early to such a court are: should fluorocarbons be banned because of their effect on the ozone layer? Should water supplies be fluoridated? Should a specific nuclear plant be licensed?

The working party's interim report (in *Science*) has the clear implication in its opening paragraph that a Science Court, by sticking closely to what can be factually established, will be able to hand over something useful to the decision-makers of society, who will then incorporate social value questions. A scientific fact is defined as a result, or an anticipated result, of an experiment or an observation of nature. On the other hand, the report continues, "we have no illusions that this procedure will arrive at the truth, which is elusive and tends to change from year to year." Thereby the science court neatly ducks the issues and relegates science to a backroom, purely technical rôle.

The scientist is most unlikely to be able to deliver to the decision-maker any useful sort of factual statement, because he is hardly going to be allowed to perform the appropriately large experiment or observation. All he can generally supply in the way of facts is some results from pilot projects, some calculations which may be relevant and so on. What the good scientist should also be competent to provide, however, is inference, and this, albeit tentative and hedged-about, is what the decision-maker needs and what the science court seems to avoid.

Factual statements of the highest presumptive validity would merely be about rats, about rocket samples, about tensile strengths. Those involved in public policy need to know whether, in the scientist's best judgment, such statements can be generalised. Intelligent customers for these sorts of judgments know full well that scientific 'truth', being a whole level higher than facts, is often every bit as elusive and changeable as political and economic 'truth'. But they still expect the scientist to go beyond the solid ground of his facts.

It is difficult to see that a science court has anything new to offer if it steers clear of this territory—indeed the exercise could be positively dangerous in that others, less qualified, may be tempted to draw their own conclusions from such handily accumulated and uninterpreted facts. □

More than judgments, action?

THE best debates never die. As the arguments about nuclear power continued in Britain last week with the resumption of the SGHWR enquiry by the House of Commons Select Committee on Science and Technology, life was again being breathed into a still more fundamental (though still less newsworthy) debate—the centuries-old argument about the depletion of the Earth's natural resources. It came with the publication of *Materials and Energy Resources*, the report from a three-year-old working party on resources embraced by the UK Institution of Chemical Engineers (I.Chem.E.).

At £5 it is a costly two-score pages, not helped by the I.Chem.E. wanting, apparently, to have its cake and eat it. It is both seeking to stimulate reasoned discussion on crucial resource problems and trying to get something done about them. Thus, while the report rightly points out the vital need to see materials and energy problems as two sides of the same coin, and traces the broadly-based working party's own valuable assessments of these problems, it is also being presented as an attempt to influence policy. Not, though, general resources policy internationally, but specifically, and as a matter of strategic importance, UK government policy.

That is laudable enough, perhaps, but represents a curious disposition for such a study from such a body. After all, the disciplines it represents and the problems it is tackling are nothing if not international, as are the phenomena like international cartels which it acknowledges. Since it also focuses its attention on a period 10 to 35 years hence (by which time, if the past is anything to go by, the world order ought to have changed), the working party might have done better to look more closely for international solutions.

Not that it has done wrong in sending the report to the Secretaries of State for Energy, Industry and the Environment. But, in spite of what was described enthusiastically last week as a positive response from Industry, the fears being expressed privately that the report could easily lose itself in the bureaucracy are more than justified. The I.Chem.E., which probably wants simply to be a professional group turning out professional work, ought to leave both this problem and the job of actually campaigning for changes in policy to the pressure groups.

The present importance of the nuclear issue, in the UK and elsewhere, is not a little due to fringe groups making effective use of the information and judgment from reputable bodies ill-placed if not disinclined to deploy it themselves. The resources issue ought to be next. The best debates never die. □

Seveso: the aftermath

Alastair Hay reports on developments since a
chemical explosion rocked this northern Italian town

Four-year-old Séveso victim

THREE months have elapsed since the now notorious Séveso accident of July 10. It occurred when a reactor producing trichlorophenol at the ICMESA chemical plant—owned by Givaudan, a Hoffman-La Roche subsidiary—became overheated: the rapid pressure increase that followed led to the discharge of its contents through a safety valve directly into the atmosphere. Scientists have since been engaged in decontamination work in the area, which was affected by the fallout of TCDD (2,3,7,8-tetrachlorodibenzo-para-dioxin) as the disastrous consequence of that discharge. A considerable amount of disturbing information has now come to light concerning both the operation of the ICMESA plant, and the decontamination procedures adopted.

Givaudan began to produce trichlorophenol at the ICMESA plant only in 1975. The monthly output of the plant was 5 tons but, in producing this quantity of trichlorophenol, the reaction also produced 1.2 kg of dioxin. This, according to an Italian trade union document, is the quantity which ICMESA was required to dispose of every month. It represents a high level of dioxin formation, of the order of 200 p.p.m.

According to a report in *The Times* earlier this week, however, Dr Donald Lee, the British expert now investigating the accident, is thought to have told the Italian authorities that up to 130 kg of dioxin could in fact have been produced in the explosion. His recommendations are said to include the suggestions that residents should have medical tests for the rest of their lives, that the contaminated area should be monitored for decades, that this and a buffer area should be sealed off to all but authorised personnel, and that decontamination procedures should involve the creation of forests and dismantling of buildings rather than the shifting of earth and the washing of buildings.

Although a senior Roche executive says, according to the Italian weekly *L'Espresso*, that the company was producing TCDD deliberately for military purposes, Givaudan has denied the allegation. But Professor Fritz Mori, designer of the trichlorophenol reactor at ICMESA, has referred to the cause of the dioxin formation through a sudden rise in temperature within the reactor and gone on record as saying it would be impossible "unless the reactor was being used to produce substances other than the trichlorophenol it was designed to produce". The design of the reactor involved in the accident has come in for severe criticism, for incorporating safety features inadequate for the production of chlorinated phenols.

Information possibly vital to the resolution of the problems of plant operation, design and safety, however, is still not available to the Italian authorities. As for the estimate that the residents of Séveso and its surrounding area will not be allowed to return to their homes for at least a year, this is regarded as optimistic by many scientists. Although vegetation from the less contaminated zone is now being incinerated, no specific plan for removing dioxin from the soil has yet been agreed. Originally, topsoil from the total area contaminated was to have been cleared and processed to remove dioxin. However, some recent tests have revealed dioxin at a depth of 25 cm. The original proposition, which relied on TCDD being close to the surface, is now considered to be too difficult an undertaking, and operations will be confined to removing dioxin from the 30–40 hectare zone most severely contaminated.

Antidote claimed

Givaudan claims to have developed an antidote which will destroy the dioxin, consisting of an olive oil–water emulsion and cyclohexanone. In principle, the dioxin is detoxified by rupture of the linked ring system and the removal of the chlorine atoms by the unsaturated bonds of polyunsaturated fatty acids present in the olive oil. Ultraviolet light absorbed by the cyclohexanone initiates the reaction sequence. However, the Italian authorities, as well as American and British scientists, are sceptical about the success of the Givaudan claim. The Italians and Americans maintain that there is no effective antidote for TCDD. And Professor Derek Bryce-Smith of Reading University says sunlight does not contain a high proportion of ultraviolet in the wavelength range where cyclohexanone absorbs it. Although the photochemical reaction may take place in the laboratory, there is, he says, a real danger of moving dioxin so that it is harder to get to.

TCDD is virtually insoluble in water, and for this reason is not translocated rapidly in soil. Placing a dioxin solvent on the soil—TCDD is partially soluble in organic solvents—could obviously assist in moving the dioxin to greater depths. Another complication is the fact that cyclohexanone is itself a dangerous chemical: its flash point, only 63 °C, is well below its boiling point of 155.6 °C; in terms of human toxicity, it is considered a weak narcotic, and it also irritates skin and mucous membranes; the lethal dose for mice is 8,000 p.p.m. in air.

The reports causing most worry, though, are those concerning the results of the blood tests carried out on the ten thousand residents of the Séveso area. Information not yet released by the Italian health officials confirms that 5–10% of the people examined are showing reduced white cell blood counts. Although it is only three months since dioxin was released, and a reduction in blood lymphocyte count is a secondary effect of damage to the immune response tissue—which dioxin is known to affect—these results are causing great concern. The situation is expected to worsen, and more residents may show adverse clinical symptoms; persons already affected could record a further reduction in their white cell count. But some scientists who have recently returned to the UK after visiting Italy feel that symptoms of dioxin poisoning are less serious than was originally feared.

Given the known teratogenic properties of dioxin, 150 women from the Séveso area who were in the first trimester of pregnancy at the time of the explosion have applied for an abortion. By the end of September, 25 women had received government authorisation for the operation, in the face of great opposition from the Catholic Church. Authorisation for another 125 women is also likely.

Health officials have examined a total of 730 pregnant women formerly resident in the contaminated area. The difficulties in securing legal abortions have added considerable impetus to the campaign for abortion law reform; the Italian parliament is to consider several bills advocating changes.

In view of the known toxicity of TCDD and the knowledge that it is a constant by-product of the trichlorophenol manufacturing process, many scientists are now beginning to question the need for the continuation of trichlorophenol production. One of the two

The possible alternatives

THE available alternatives to 2,4,5-T are 'Amcide', 'Glyphosate' and 'Krenite'; all three are effective brushwood killers. Amcide has been available in the UK since the early 1960s; Glyphosate is a more recent addition, and Krenite is at present only on sale in the US and West Germany.

These alternatives, when compared with 2,4,5-T, have some definite advantages. Amcide, made by Nissan in Japan, has an LD_{50} value for rats of 3,900 mg kg^{-1}; Glyphosate, made by Monsanto, has an LD_{50} value of 4,900 mg kg^{-1}. These toxicity ratings are well below that for 2,4,5-T (LD_{50} value 300 mg kg^{-1}). Krenite, made by Dupont, has an LD_{50} value of 24,000 mg kg^{-1}, a toxicity rating one eightieth of that for 2,4,5-T.

The reaction to produce Amcide presents none of the potential hazards associated with trichlorophenol manufacture in terms of toxic by-products. Information has not been made available for Glyphosate or Krenite production. However, in the case of Krenite the US Environmental Protection Agency (EPA) considers its manufacture to conform to accepted safety standards, and in view of its comparatively low toxicity has declared it as safe for use even on land adjacent to domestic water supply reservoirs and streams.

The disadvantages associated with the three alternatives are primarily those of cost. Amcide and Glyphosate are more expensive than 2,4,5-T when the concentrations of herbicide necessary to effect the same plant kill ratio are considered; Glyphosate is nearly five times as costly. Some potential buyers of Krenite consider that it, too, may be expensive when it is introduced on the UK market. The only other problem of any consequence relates to Amcide. In contrast to 2,4,5-T which is absorbed through leaves following spraying, Amcide must be applied to cut surfaces on plants. Its method of application is therefore considerably more labour intensive.

Hexachlorophene, the other major product derived from trichlorophenol, is a general poison effective in the control of gram-positive bacteria. In the cosmetics industry hexachlorophene is used as a preservative. For medical purposes hexachlorophene is used in the control of staphylococcal organisms. The bactericide has four main uses: treatment of acne and impetigo, cleansing of intact skin around burns or wounds, pre-surgical washing, and cleansing of new-born infants, particularly the umbilical cord.

Its use, however, has been much reduced, and the industry is reported as being able to dispense with it altogether. Chlorhexidine—a bactericide now cleared for sale in the US—is used surgically in the UK as a skin cleanser, wound steriliser and for pre-surgical washing. On the question of the cleansing of the newly-born infant, however, there is a difference of opinion as to which of the two bactericides is the most effective.

Maternity clinics and nurseries are particularly open to bacterial cross-infection by the staphylococccal organisms. One of the most common is *S. aureus*. In the 1940s this organism was responsible for frequent epidemics in nurseries, with a consequent increase in infant mortality. When hexachlorophene was first marketed by Givaudan in the late 1940s it proved to be effective both in the routine containment of *S. aureus* and in controlling the organism in the case of an epidemic. As a result of its efficiency, hexachlorophene rapidly replaced the bactericide 'Triple Dye' in use at that time, to become the most widely used anti-bacterial agent in nurseries.

Two events in 1971 and 1972, however, caused users to reconsider their judgment. The first was a report by the EPA showing hexachlorophene to cause oedema and hindlimb paralysis in experiments on mice. The second was the death in France of 35 infants following the use of talcum powder containing 6% hexachlorophene. The neurological damage which led to the death of the children was caused by a twenty-fold increase of hexachlorophene concentration in the talc, the result of a manufacturing error.

Many maternity units in the UK have since reduced the amount of hexachlorophene used for infant washes. Currently less than half use hexachlorophene at all. Others rely on alcohol, used either alone or with chlorhexidine. Consultants at one cross-infection laboratory now recommend nurseries to avoid the use of hexachlorophene altogether for routine washes. The reasoning behind this recommendation lies in the evolution of *S. aureus* itself, which has evolved through several forms since the 1940s and is now active as a complex of *S. aureus*.

The present generation of the bacterium is not causing serious epidemics in British hospitals which are fatal to children. Indeed the risk associated with hexachlorophene use is considered to present a greater threat than that represented by the staphyloccus itself. A further consideration is the fact that many British maternity units use a concentration of hexachlorophene to control *S. aureus* which is too low to kill the bacterium.

In the routine control of *S. aureus* chlorhexidine is as effective as hexachlorophene, and has the added advantage of an LD_{50} value ten times higher. Chlorhexidine is also reported to be just as efficient in controlling local epidemics of the present milder strain of the bacterium. It has not been tested, however, with more lethal strains of the staphylococcus, whereas hexachlorophene has been shown to control dangerous epidemics of *S. aureus* in the past. Some bacteriologists anticipate that chlorhexidine will prove to be equally effective, but are reluctant to recommend it unequivocally as an alternative until this has been demonstrated conclusively.

Although the principal purpose behind trichlorophenol production is the synthesis of 2,4,5-T and hexachlorophene, the chlorinated phenol is still used to some extent as a slime control agent in the paper-making industry. It has never been as popular as pentachlorophenol, used for the same purpose, and what use it has had has been much reduced, due mainly to the criticisms of the unrestricted industrial use of polychlorinated biphenyls (PCBs) such as DDT, advanced by the environmental lobby.

In common with many industries which discharge effluent directly into rivers, the paper manufacturers have been particularly sensitive to the charge that their plant operating procedures are damaging to the environment. Because of the known risks associated with extensive PCB use, paper manufacturers in the UK have considerably reduced their use of all chlorinated phenol derivatives. Agents now preferred for the prevention of fungal growth include methylene *bis* thiocyanate together with some organobromine and organosulphur products.

products derived from trichlorophenol —the herbicide 2,4,5-trichlorophenoxy-acetic, 2,4,5-T (the other is the bactericide hexachlorophene) — has many formulations which contain the dioxin contaminant. In view of this the Norwegian authorities banned the use of the herbicide altogether in 1973. The US Environmental Protection Agency (EPA) regards 2,4,5-T as a product which may be too hazardous to man and the environment to permit continued use.

In the UK, however, the Ministry of Agriculture, Fisheries and Food's 1976 "List of Approved Products for Farmers and Growers" contains five formulations of 2,4,5-T alone, and eight of 2,4,5-T in combination with 2,4-D (2,4-dichlorophenoxyacetic acid). These products are sold as bramble, brushwood and nettle killers. A new formulation of 2,4,5-T, 'Silvapron T', produced by British Petroleum, is currently on trial in Britain. The herbicide is dispersed in an oil-based mixture which

The cost mounts

avoids some of the problems of volatilisation encountered with the traditional water-based mixtures. This BP formulation is restricted to forest areas.

Neither product unique

But neither 2,4,5-T nor hexachlorophene is unique. Alternative herbicides and an equally effective bactericide are available (see box). Because of this, many scientists now question the desirability of using a reaction as dangerous as that involved in synthesising trichlorophenol. They point out that, with one exception, every plant producing trichlorophenol has had a serious accident involving release of dioxin, and injury to workers and the general public. The list of accidents begins with Monsanto (US) in 1949; then comes Badische Anilin und Soda Fabrik AG (West Germany) in 1953, Philips Duphar (Holland) in 1963, Dow Chemical Company (US) in the early 1960s, Coalite and Chemical Products Ltd (UK) in 1968, and finally, Givaudan-ICMESA (Italy) in 1976. Bayer of Leberkusen (West Germany) is the sole apparent exception.

But it is not only scientists who are concerned about the operation of the trichlorophenol process. The Italian authorities have invited Givaudan to build a new chemical plant near Séveso, with the provisos that it utilises reaction processes known to be safe and that trichlorophenol is not produced. Two other manufacturers of trichlorophenol are equally concerned; the Coalite and Bayer plants have both temporarily ceased operation. Additional safety features are to be introduced at Coalite as a result of recommendations by the UK Health and Safety Executive, but forty-nine of the fifty workers have refused to work there under any circumstances.

The trichlorophenol manufacturing process is only one of the potentially

hazardous operations which will now come under closer scrutiny as a result of the devastation at Séveso. There are few processes which can have the unique record of an almost one-to-one ratio of accidents to production sites. However, there may be some where the value to society of the products manufactured is not sufficient to justify continued operation. The disaster in Italy will provide the backcloth for the debate which could help to resolve these issues.

● Yet another release of a dangerous chemical occurred in Italy on 26 September. This time between 10 and 30 tonnes (according to different sources) of arsenious oxide "escaped" from the ANIC chemical plant—a subsidiary of the Italian state fuel concern ENI—near Manfredonia on the Adriatic coast.

Over fifty people including two infants have been hospitalised with suspected arsenic poisoning (LD_{50} for rats is 138 mg kg^{-1}). The ANIC plant management only admitted the risk to local residents when the results of tests carried out by health officials confirmed a serious pollution hazard. The mayor of a town in the affected area appealed to the Italian government for assistance; no response came for several days. ANIC officials now say all but 1 km^2 of the area has been rendered harmless.

This has been done by spraying with calcium chloride and ferric sulphate solutions. When arsenious oxide is in a soluble form these two additives will form complexes of calcium pyro-arsenite and ferric enneaoxyarsenite respectively. Both complexes are considerably less soluble than the oxide and would thus reduce the amount of arsenic leaching into the water system and spreading far beyond the present area of pollution.

Nuclear power's litmus test

A crucial test of public confidence in nuclear power will take place in six states during next month's Presidential election. Colin Norman reports from Washington.

WHEN residents of Arizona, Colorado, Montana, Ohio, Oregon and Washington mark their ballot papers on November 2, they will do more than cast votes for candidates for sundry political offices. They will also vote on resolutions which would place strict—some say crippling—controls on nuclear power plants in their states.

The resolutions are stirring up considerable debate, and large sums of money are being spent both to promote and defeat them. Although the number of power plants affected is relatively small compared with the total number planned for the United States, the votes are regarded as a litmus test of public attitudes towards nuclear power. With the election less than a month away, opinion polls indicate that the resolutions stand a good chance of being approved in at least two states—Colorado and Oregon.

Although there are some differences between the resolutions on the ballots in the six states, they would all set three important conditions on the operation of nuclear power plants.

● There must be no limit to the total amount of damages which could be claimed by victims of a nuclear accident. At present, a federal law, the Price-Anderson Act, limits the nuclear industry's liability to a total of $560 million for each accident.

● Before new power plants could be operated, the state legislature would have to be convinced that major safety systems—including the much-discussed emergency core cooling system—would operate properly in an emergency. Approval would require a two-thirds vote in the legislature.

● Similarly, at least two thirds of the legislature would have to be satisfied that adequate, proven technologies exist for transport, storage, and disposal of radioactive wastes.

At present, it is doubtful that the nuclear industry could meet those conditions. Thus, passage of the resolution in any state would virtually rule out nuclear expansion in that state.

Voters in California were presented with a similar choice last June, when a nuclear safety proposition was placed on the ballot papers in the Presidential primary elections. That proposition, which would have imposed the same three conditions on nuclear plants in

California, was eventually defeated.

Supporters of the resolution in Oregon and Colorado, and to some extent in the other four states, expect to fare better, however. For one thing, the steam was taken out of the California campaign at the last moment when the state legislature passed a package of nuclear safety bills which included some of the proposition's requirements. But, more important, the California proposition would have applied to existing, as well as planned, power plants. The Oregon and Colorado measures, by contrast, would specifically exempt existing plants.

A potentially important factor in the vote on the Oregon resolution is that during the Oregon primary election earlier this year, Jimmy Carter, the Democratic Presidential candidate, virtually endorsed the resolution. He said that although he would not try to advise people how to vote on the matter, if he were an Oregonian, he would support the resolution. He did not endorse the California proposition, however, largely because it would have

applied to existing plants.

Supporters of the resolution also like to point out that both Colorado and Oregon have approved a number of environmental laws long before other states. Oregon, for example, was the first state to outlaw the sale of plastic bottles and aerosol sprays containing fluorocarbons, and among Colorado's environmental achievements is the passage of a resolution which stopped the Winter Olympics being held there.

But the most solid piece of evidence that the nuclear industry is in trouble in Colorado and Oregon comes from public opinion polls published early in October in newspapers in Denver and Portland. They suggested that public sympathy was then running nearly two to one in favour of the resolutions. Although that margin is sure to close as the election draws near industry officials say they are very concerned.

Thus, if the resolutions are adopted by any state this November, it would give the anti-nuclear movement a boost in future efforts. But, by the same token, if the resolutions are defeated, the nuclear industry could claim a vote of confidence. Clearly, the stakes are high.   □

GAO knocks ERDA

Although the Energy Research and Development Administration (ERDA) is responsible for developing nuclear energy technologies in the United States, ERDA officials insist that they have not tried to influence the outcome of the referenda on nuclear safety being held in various states. Those assertions are, however, called into question by a report published last week by the General Accounting Office (GAO), an investigative agency of the US Congress.

According to the report, between February and April 1976—when debate on the California referendum was raging—ERDA distributed 78,600 copies of a pro-nuclear pamphlet in California. According to GAO, the pamphlet "was not objective, is propaganda, and was not a proper document for release to the public". The pamphlet was used by the nuclear industry in California in their campaign to defeat the California proposition.

ERDA officials have claimed that the document—a series of so-called myths and facts about nuclear power—was prepared solely for internal distribution within the agency. It was intended, they have argued, for employees in the controversial liquid metal fast breeder reactor pro-

gramme, to help answer criticisms of the programme and to lift morale.

GAO found such assertions hard to swallow, however, since the fast breeder programme employs only about 6,700 people, yet 100,000 copies of the pamphlet were printed. Moreover, GAO found it difficult to understand why the bulk of the copies were sent to California, while most of the breeder reactor work is going on in other states.

Nevertheless, GAO stopped short of actually accusing ERDA officials of trying to influence the California vote—in fact, it specifically states that it could find no such evidence and suggested that ERDA officials had not actually violated any laws. The report did not attempt to explain why so many copies of the pamphlet were distributed in California at that particular moment, however.

As for the quality of the pamphlet, the GAO report suggested that it was so superficial and misleading that it was not even suitable for distribution to ERDA employees as part of morale lifting effort. "ERDA should not place itself in the position of misleading others—whether it be the public or its own or contractor employees—for the sake of raising morale", the report argued.

CANADA

A matter of judgment

David Spurgeon writes from Ottawa on a report covering Canada's problematic science-industry relationship

IN 1973, the Ministry of State for Science and Technology (MOSST) introduced a "Make-or-Buy" policy, the aim of which was to increase the proportion of government-funded research and development (R&D) carried out under contract by industry as opposed to government laboratories. The government hoped to strengthen the innovative capacity of Canadian industry and to enhance its competitive position. The policy has not generally been regarded as a howling success, especially by industrialists. In the year following its introduction, in fact, the Cabinet found it necessary to expand the original policy to allow financing of unsolicited proposals for R&D from the private sector.

A steady decline in support has generally been seen in the government's R&D funding policies. A brief from the Royal Society of Canada to the Prime Minister said that, although it was generally recognised in 1969 that government support for industrial R&D was already too small, it is now even smaller: in terms of the fraction of federal budgetary expenditures it had fallen by 1975 to 68% of the 1969 level.

Now a report has come from the MOSST* conveying the message that the Make-or-Buy Policy has in fact been rather successful, and that more of it is needed. The report is full of statistics supporting its argument, but its general tone appeared so contrary to what could be heard in non-government quarters that it left the impression of being a rather curious document.

A little investigation suggests why: the choice of statistics is highly selective, some say misleading. In fact it is questionable in some cases whether they show what they are purported to show. One table, for example, shows the increase since 1973-74 of mission-oriented contracts awarded to industry by the Department of Supply and Services on behalf of the various government departments, the intent being to indicate that they have increased. Yet the table lumps together all contracts from government departments, as though all resulted from the policy. In fact government departments have contracted out to industry for years, to a greater or lesser degree.

One diagram showing payments to Canadian industry for R&D between 1963-64 and 1975-76 shows not only that research contracts have increased since the Make-or-Buy policy was initiated, but also that, years before, in 1965-66, such contracts were larger than any year until 1973-74, indicating that the grants level fluctuates from year to year, and that taking just a short-term view (that is, from 1973-76) can be misleading. (The year 1965-66 was a good one largely as a result of the hydrofoil project of the Department of Defense.)

Analysis of the figures used in the report actually shows that government R&D contracts to industry had already begun to rise *before* the Make-or-Buy policy was put into effect, and, plotting them on a graph, that the level of R&D contracts to industry would be at the same point they reached even if they had merely been extrapolated at their former rate.

Furthermore, the ratio of payments to industry vs. intramural R&D was less in 1975-76 than a decade earlier by a substantial margin (even though that was only for a single year). Even since the Make-or-Buy policy was introduced, the increase in industrial contracts has amounted to only roughly $20 million, while the increase in in-house research funds has amounted to $57 million. And in terms of overall science expenditures by the federal government, industry's share has fallen from 19% to 16% during the three-year period of the policy.

The report, which was only released this summer, admits that it is premature to assess whether the ultimate economic effect aimed for in the policy is yet being achieved. But it does claim that the policy has had a beneficial effect on several sectors of industry. At the same time, it admits that during the course of the past five years, the proportion of Canada's total resources directed at R&D has steadily declined: gross national expenditure on research and development as a percentage of GNP had dropped in 1972 to 1.14% from 1.29% in 1969, while the Senate special committee on science policy had said it should be about 2.5% to keep Canada competitive internationally.

The report finds that the effects of the policy to date have been most pronounced in electronics, transportation and scientific services, where objectives of government and industry most closely coincide in the context of current departmental missions. If the programme were to be extended—which the report thinks advisable—either a reduction in government scientific staff or a substantial increase in funds for contracts would be necessary. □

Trudeau rings the changes

Stung by the results of a public opinion poll that showed Canada's Liberal Government to be lagging far behind the opposition in popularity, and by criticisms of both his bilingualism and anti-inflation programmes, the Canadian Prime Minister, Pierre Trudeau, recently announced wide-ranging Cabinet changes that have produced a new head for the Ministry of State for Science and Technology (MOSST).

Gone not just from the ministry, whose portfolio he held jointly with that of Public Works, but also from the government itself, is C. M. "Bud" Drury, who at 64 was one of the two most senior Cabinet members (with Mitchell Sharp, who has also resigned). In his place is Hugh Faulkner, a more junior minister who, according to the Toronto *Globe and Mail's* Ottawa correspondent, "was demoted from Secretary of State to Minister of State for Science and Technology mostly because the Liberal caucus felt that he had failed to sell bilingualism, a special responsibility of the Secretary of State."

Be that as it may, the new appointment is not calculated to cause rejoicing throughout the science community. Mr Faulkner's appointment makes it obvious that the science ministry will continue to be regarded by the government as a low priority, as it has been from its inception in 1971. Apart from Mr Drury, Mr Trudeau has always appointed inexperienced or junior ministers for this post.

The new appointment comes as just one more disappointment for the science community. But to many, Mr Drury's attitude towards the needs of science in Canada had in recent months seemed apathetic if not openly hostile. In spite of studies and recommendations on national science organisation, the government in general and Mr Trudeau in particular apparently lost interest in science and technology. The concerns of bilingualism and inflation had loomed so large as to eclipse science, and doubts had grown about the government's professed concern for the problems of science-based industry.

IN BRIEF

ESA moves

The European Space Agency's Scientific Programme Committee has approved the spending of about $115 million on two projects: a contribution to NASA's space telescope, due for launching in 1983, and the Geosari project involving the Geos spacecraft and Ariane launcher.

The $104 million provisionally allocated to the space telescope will provide 15% of the costs of the telescope and its associated Science Institute. In exchange European astronomers will get at least 15% of total observing time.

Negotiations with NASA on another ESA/NASA cooperative project, the Out-of-Ecliptic Mission, will continue. LIRTS (Large Infrared Telescope on Spacelab) and several other projects will be considered in the spring.

The council of the European Space Agency has appointed a new director of the Spacelab programme, M Michel Bignier. Until June 1976 M Bignier was Director General of the French Centre National D'Etudes Spatiales.

MRC report warning

The UK Medical Research Council (MRC), referring to the dual-support system for research in its annual report published this week, warns that, under extreme pressure, it would be contractually obliged to protect the security of its own 4,373 staff at its 68 research establishments, and the capital investment associated therein, if necessary at the expense of its indirect support for research at universities. Such a situation, the outgoing Secretary Sir John Gray emphasised, was not yet foreshadowed, and MRC policy remained one of parity between the two lines of support.

Government departments have redeployed with the MRC the 25% of the council's grant-in-aid from the Treasury transferred to them under the Rothschild arrangements. Total expenditure for the year amounted to £47.18 million, up 30%, of which international subscriptions, which grew 66%, were £960,000. Increases in these subscriptions because of exchange rate variations, along with pay and associated awards, made three additions to the grant-in-aid necessary. The current doctrine of cash limits, said Sir John, meant that any extra money to meet international obligations would have to come from ongoing work.

SGHWR inquiry continues

Following the summer recess, the UK House of Commons Select Committee for Science and Technology has resumed its inquiry into the decision surrounding Britain's involvement with the SGHW reactor with evidence from the Central Electricity Generating Board (CEGB) last week and from the United Kingdom Atomic Energy Authority (UKAEA) earlier this week.

In another development, a report from a study group chaired by Dr Walter Marshall on the integrity of pressure vessels for light water reactors was published by the UKAEA last week. The 156-page report makes 40 "essential recommendations" and has buttressed the case for PWRs and against SGHWRs in Britain.

THE pertinacity of the promoters of laetrile for cancer "cure" is probably related to the amount of funds at their disposal. Some possible clues are in a grand jury indictment in California, stating that 10 ml of laetrile, sufficient for three daily injections, cost American cancer patients as much as $60 and that a physician who administers laetrile "as a vitamin supplement" deposited $2.5 million in northern California bank accounts between May 1974 and August 1975. The president of the Committee for Freedom of Choice of Cancer Therapy was arrested last December with $40,000 worth of laetrile in his car, along with a loaded Browning automatic pistol. Previous cancer remedies such as Krebiozen and the Hoxsey remedy were on a smaller scale. The big question is: will political pressure, financed by profits from laetrile, overcome the opposition of organised medicine to its legalisation?

The Merck Index describes laetrile as the β-glucuronide rather than the β-glucoside, of L-mandelonitrile. It seems probable, however, that the laetrile of "underground commerce" is actually amygdalin (the β-glucoside). An argument used by the pushers of laetrile is that it is "vitamin B_{17}". In support of this, one of them stated that "it becomes almost impossible, on the negative side ever to declare scientifically that a compound is not a vitamin . . .". Constance Holden, a staff writer for *Science*, echoing this statement, said on September 10, that "no one has really been able to prove" that there is no such vitamin (as B_{17}). She also said that it is a "fact that scientists are not able to defini-

Laetrile struggles

THOMAS H. JUKES

tively refute the nutritional claims about laetrile . . .". Actually nutritionists feel no inhibitions about refuting such claims.

The cyanogenic glycosides, including amygdalin, have no resemblance to vitamins. The accepted definition of a vitamin is that it is necessary in the diet of at least one vertebrate organism to prevent a specific deficiency disease. The Committee on Nomenclature of the American Institute of Nutrition found no scientific evidence (i) for the existence of a nutrient identified as vitamin B_{17} or (ii) that laetrile has nutrient properties or nutritional value for "either animals or humans" (*sic*). Cyanogenic glycosides are often poisonous to livestock. One of them, linamarin, is present in cassava, and sometimes causes human blindness.

The persistent efforts of laetrile proponents were successful in Alaska where, on June 21, 1976, Governor Hammond allowed the "Laetrile Bill" to become law, thus permitting physicians to prescribe laetrile. His excuse was an implementation of the "equal time for nonsense" principle, which says that if there are two sides to an issue, it is not the role of a statesman to decide which one is right. The history of scientific medicine as applied to public health shows that it is insufficient to make discoveries that benefit human beings. It is equally important to get rid of quack remedies to make room for new advances. Until recently, legislators accepted informed advice in framing public health laws, but Alaska is "different".

The latest news is fascinating: the Assistant Attorney General of Alaska now says that sale or distribution of laetrile in Alaska by any person, including a physician, is illegal. There may be a problem in filling those prescriptions.

correspondence

Future of journals

SIR,—Your editorial of August 26 (p. 731) on the future of journals is typical of the current negative attitude to the problem. It is a pity that the more constructive contribution on the subject from Professor May and his wife (*Nature,* February 12, p. 446) was not mentioned.

The rising costs of running a library are eating into the money available for the purchase of publications, and yet we constantly read that there are too many journals, never too many librarians. The main library is often rightly the showpiece of the modern university campus, but are all librarians aware of their primary responsibility? Rows of expensively bound journals may satisfy the eye, but a drawer or binder of microfiche could be more relevant to academic needs.

The "pious hope" that two journals might be shut down for every new one launched would not be considered particularly pious by the users of the two guillotined journals. It would be more sensible in the short term to cut down on costs on both sides, amalgamate smaller, ailing periodicals and employ new methods such as those pioneered by the chemical societies in the United States and Britain.

We gather from various journal publishers that despite the economic conditions prevailing in many countries, reasonably priced research journals of medium circulations (1,000–4,000 subscribers) have generally enjoyed a steady increase in circulation, which has been maintained this year. This is an inevitable result of the worldwide growth of the academic community, and possibly also of the rationalisation of library purchases; for example, a university which may take 10 subscriptions to a major journal, or an 'essential title', for various departments, might cut down to two for the main libraries (*Nature* beware!), thus releasing funds for new acquisitions.

The long-term result of this trend might well be a huge number of journals distributed to, say, 1,000 resource/information centres scattered around the world. Researchers would then obtain photocopies of original papers, having browsed through synopses and abstracts, at their local library, by then reduced to little more than a post-office. This surely could lead to delays of a week or more. Faced

with such a possible outcome perhaps researchers and librarians might learn to love cabinets of microfiche.

May we therefore suggest that the present number of 35,000 journal titles should be viewed as a challenge, and not approached with despair. The final suggestion in your editorial, that authors should supply full details on request, would be a long step backwards. Imagine trying to trace an author from his last known address; with the present postal services it could take months. Who would be prepared to referee papers which might never be read? What use would data lists be in job applications? Evidence could be altered at a later date as no dated record would exist. Such chaos should be avoided. More organisation is required, not less.

SIR,—I should like to comment on your editorial about the future of journals (August 26). As librarian in a research laboratory, I would agree with most of what you say—with the proviso that the changes you refer to should be reflected not only in journal subscription price, but in volume of paper. This is conspicuously not the case in the experiment of the American Chemical Society, where the weight of paper is much higher in the experimental than in the traditional journal.

As a practising organic chemist, I must, however, reply a firm "no" to your last question. Chemistry in general, and organic chemistry in particular, is an experimental science, and we must have the experimental detail readily available. One of the greatest weaknesses of the *Bulletin de la Société Chimique de France* was that experimental sections were abbreviated to the point of irreproducibility, although things have improved recently. There is a large body of opinion (perhaps even a majority) which recognises that theoretical sections are usually fitted to experimental sections after the event; and indeed, what some would like to see is a journal in which only the experimental section and the literature list is printed, the theoretical section being available on microfiche if the reader were unable to supply his own!

Mistaken impression

SIR—I fear that Wil Lepkowski, in quoting from a paper that I presented at the Conference on Tradition and Change in Physics Graduate Education at Pennsylvania State University in August 1974, may have inadvertently given a mistaken impression of my position (August 12, page 528).

As I state in the same paper, "The Berkeley Group missed out on making these discoveries not so much in spite of the fact that their laboratory was so large, efficient, well-run and well-managed as precisely because of it".

The purpose of my paper was not to criticise a particular laboratory, but to argue, on the basis of historical experience, that the techniques of "Big Science", while they may be useful in solving certain engineering problems, as in the case of the Manhattan Project or the Apollo Program, are by their very nature not conducive to the making of fundamental, new scientific discoveries. Condensations of my paper were published in *New Scientist,* **63,** **462** (1974) and *Center Magazine,* 55 (May–June 1975).

Biological fly killer?

SIR,—The news on Human Trypanosomiasis Today by F. E. G. Cox (*Nature,* August 19, p. 646) calls for some views. As long as the immunological control of sleeping sickness remains unlikely, eradication of the genus *Glossinia* seems to be the only way to control the disease. Cox cited recent successes in Nigeria where a riverine area of 27,500 km² was sprayed aerially. The same technique was recently used over parts of Bangladesh in an attempt to control mosquitoes. The disappearance of quite a number of insect species was subsequently noticed, though all of them may well have made a come back, and for sure the mosquitoes did. Bearing in mind the delicacy of ecological balances nobody should be satisfied with aerial spraying as a method of controlling insect species. Intensive efforts should be mounted to introduce methods of biological control, such as releasing specific pathogens.

Non-histone proteins and transcription

from Carol K. Klukas

THE genomes of mouse and of humans, having molecular weights of 3×10^{12} daltons each, contain enough DNA to code for thousands of genes. Some of these sequences are present in multiple copy form while others are included only once; some are transcribed in all cells and their presence is essential for proper cell function while others code for proteins of more limited function and are transcribed only in certain specialised cells, or perhaps only at specific times in the development of an organism or even only at specific phases in the cell cycle; some sequences code for proteins which eventually must be produced in very large quantities in a cell while other sequences will dictate the synthesis of only a few protein molecules. How is it that all the sequences can be sorted out and be transcribed or not transcribed in just the right quantitative and temporal manner to result in proper function of a cell and of an organism? What factors are involved in the control of eukaryotic genome expression?

Since the answer to this complex question must lie at least in part in the composition and structure of chromatin (the DNA with the histones and non-histone proteins which are complexed with it *in vivo*), much current research is designed to answer various specific questions concerning chromatin. Three papers published back to back in the July issue of *Biochemistry* are noteworthy examples of such research.

In each of these papers, RNA transcription *in vitro* from isolated chromatin is compared on several criteria with *in vivo* transcription to determine whether *in vitro* transcription is a faithful representation of transcription as it occurs in the cell. Once this has been established, the composition of chromatin can be changed in a controlled way and the resultant changes in transcription can be analysed. This approach should reveal which aspects of chromatin composition and organisation are essential for the maintenance of *in vivo*-like transcription.

In the first of the papers, Bacheler and Smith (*Biochemistry*, **15**, 3281; 1976) compare total *in vitro* synthesised transcripts of mouse liver chromatin with nuclear RNA by means of RNA excess hybridisations with small amounts of radioactive mouse DNA which has been fractionated on hydroxyapatite into three classes each differing from the others in the reiteration frequency of the sequences it contains. The results of these experiments indicate that all sequences found in nuclear RNA are also transcribed *in vitro*. Furthermore, the transcription of reiterated sequences from isolated chromatin is restricted in just the same way as is transcription *in vivo*, that is, highly repetitious sequences in mouse DNA are not represented in either nuclear RNA or in RNA transcribed from chromatin *in vitro*. Competition experiments show that there are sequences transcribed *in vitro* from chromatin which are not present in nuclear RNA. But these belong to a very limited set of sequences unless the chromatin is extracted with 0.5 M NaCl before transcription. This salt extraction, which strips the chromatin of H1 histones as well as of certain non-histone chromosomal proteins, results in transcription which is no longer sequence restricted. Thus, Bacheler and Smith show that at least some significant aspects of *in vivo* transcription can be preserved *in vitro* and can be altered by salt extraction, suggesting the importance of H1 histone and/or of some of the acidic chromosomal proteins in transcriptional control.

Quite a different way of analysing *in vitro* transcripts, which is used in the other two papers (pages 3291 and 3296), is to assay for the presence of transcripts of one specific gene or set of genes, in this case the histone mRNAs. Stein, Reed and Stein have prepared ³H-cDNA complementary to histone mRNA and used it in hybridisation experiments to probe for histone mRNA in transcripts from various reconstituted DNA–chromatin complexes prepared *in vitro* from fraction-

ated HeLa cell chromatin. These studies show that naked DNA is an effective template for *in vitro* transcription of histone genes (see also Huang *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **48**, 1216; 1962; Allfrey *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **49**, 414; 1963) but that this transcription is inhibited nonspecifically by the addition of histones. Further, non-histone chromosomal proteins mixed with DNA in the *in vitro* system have no effect at all on the rate of histone gene transcription or on the frequency of histone mRNA in the transcripts unless however the non-histone proteins are mixed with the DNA in the presence of histones. In this last instance histone mRNA genes are made selectively transcribable, and thus histone mRNA represents a higher percentage of the total transcript. This result indicates that the interaction of histones and non-histone chromosomal proteins must be involved in a significant way in the control of specific gene transcription in this system and as the same effect of non-histone proteins has been observed in globin gene transcription (Paul *et al.*, *Cold Spring Harbor Symp. quant. Biol.*, **38**, 885; 1973; Barrett *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 5057; 1974; Chiu *et al.*, *J. biol. Chem.*, **250**, 9431; 1975) it is quite likely that histone–non-histone protein interaction is a general transcriptional control mechanism.

In these experiments the chromatin used was isolated from HeLa cells in the S phase of the cell cycle. In the last paper (page 3296) Park, Stein, and Stein investigate the *in vitro* transcription of G_1-phase chromatin and report that they find very little histone mRNA in the transcripts. But if S-phase chromosomal proteins are added to G_1-phase chromatin, the specific transcription of histone genes is enhanced. When G_1 and S-phase chromatins are fractionated and reconstituted using combinations of pooled DNA and pooled histones with varying amounts of G_1 or S-phase non-histone proteins, it becomes clear that S-phase chroma-

tin contains a non-histone protein which has the ability to render the histone genes available for transcription. It is the absence of the protein in G_1-phase chromatin rather than the presence of some inhibitor molecule which distinguishes G_1-phase from S-phase chromatin. Thus the importance of the non-histone proteins and their interaction with DNA and histones in the control of specific genes is again indicated.

The type of *in vitro* transcription and reconstitution experiments presented in these papers are beset with difficulties not only in their execution, but also in their interpretation. Often such work meets with much criticism and scepticism because factors such as just how the DNA probe was made and how the reconstitution and hybridisations were performed can alter the results significantly and consequently lead to misinterpretations. Also one can always criticise this type of work by pointing out that the studies are after all *in vitro* and may have nothing to do with the transcriptional process which occurs in the cell. Certainly this is correct; however, *in vitro* transcription and reconstitution experiments despite their difficulties are useful in pointing out which components of the *in vivo* system may be of particular significance. In a system as complex as that for the control of eukaryotic genome expression, such clues to which factors are likely to be most important is certainly useful as a guide for further thought and research. ☐

Higher ozone concentrations over Britain

from Peter D. Moore

THE elevated levels of ozone in the atmosphere of London and other parts of Britain have been a source of concern for some years (see *Nature*, **256**, 537; 1975). Man-made pollution is undoubtedly a major source of ozone in the troposphere and inflates the 2–4 p.p.hm. which is normally found there. Petrol and diesel engines are considered to be important in this process of ozone generation, for they emit nitric oxide and also uncombusted hydrocarbons which oxidize the nitric oxide to nitrogen dioxide. NO_2 is liable to photochemical dissociation in daylight leading to the generation of atomic oxygen which interacts with molecular oxygen to produce ozone, O_3.

Ozone is a powerful oxidant and is known to damage both animal and plant tissues (Bell and Cox, *Environ. Pollut.*, **8**, 163; 1975). The Environmental Protection Agency of the United States has established an air quality standard of a maximum ozone concentration of 8 p.p.hm. for an hour's duration. In London, the Greater London Council's guideline has been set at the same level.

For some years this guideline has been exceeded, usually during anticyclonic periods in summer. On July 13, 1972, a peak value of 11 p.p.hm. O_3 was recorded in Central London (Derwent and Stewart, *Nature*, **241**, 342; 1973). On page 580 of this issue of *Nature* Ball presents data for the summer of 1975 in London and registers a peak value of 15 p.p.hm. on June 26, 1975, almost twice the GLC guideline level. This is the kind of concentration at which, according to the WHO and the US Department of Health, a degree of eye irritation and aggravation of respiratory diseases may be expected.

This is still well below the 28 p.p.hm. of Sydney, over 30 p.p.hm. in Tokyo and up to 99 p.p.hm. in Los Angeles. It is, however, a disturbing trend. Ball has kindly provided some preliminary figures for the current (1976) summer in London which suggest that the trend towards higher ozone concentrations in Britain is continuing. Even in early May of this year, levels of 18 p.p.hm. had been recorded in London. Subsequently values up to 21 p.p.hm. have occurred, and the guideline concentration has often been exceeded for as many as 40 h per week over the whole of London. Records from Harwell are even higher than these.

Ball's data do help to resolve the question of whether Britain's ozone is largely derived from the Continent or whether our cities make a significant contribution. Cox *et al.* (*Nature*, **255**, 118; 1975) showed that photochemically generated ozone can be transported distances of the order of 100–1,000 km. Continental ozone can enter the British troposphere in sufficient concentration to raise ambient levels to as much as 15 p.p.hm., as was shown during easterly air movements at a recording station in Suffolk during August 1973. Stewart *et al.* (also in this issue of *Nature*, page 582) show that high ozone concentrations occur most often on days when the wind direction is north-east, through to south This lends some support to the contention of Cox *et al.*, but it is also true that when anticyclonic conditions prevail the wind is most often in that quarter. As Stewart shows, ozone is highest when

temperature and insolation are high, and these conditions are also associated with anticyclones. Ball now demonstrates that among the London recording stations higher values of ozone are found at those sites which receive air masses from over Greater London, and concludes that home-grown ozone represents a significant contribution to our tropospheric load.

To what extent are these recent high levels of ozone a consequence of the unusually sunny, anticyclonic summers we have experienced of late? Only continued monitoring of gaseous pollution over London can answer this. It is salutary to note that in cities like Sydney, ozone became a problem with startling suddenness. A further, unanswered question is the degree to which ozone interacts with sulphur dioxide, our other main gaseous pollutant, in its harmful effects. Menser and Heggestad (*Science*, **153**, 424; 1966) showed that tobacco plants were severely injured by mixtures of SO_2 and O_3 in concentrations of 24 p.p.hm. and 3 p.p.hm. respectively, whereas neither of these concentrations produced damage on their own. It is possible that this synergistic effect is general, in which case ozone may be an even more serious pollutant than is currently predicted, especially in cities such as London where SO_2 concentrations are still high. ☐

Pleistocene mammals

from D. W. Yalden

Historically, the evidence provided by fossil mammals played a large part in establishing the glacial theory of Pleistocene geology. The discovery in the 1860s of fossil lemmings in southern England, in particular, was readily accepted as evidence of former tundra conditions. Though early excavations of caves and river terraces concentrated on large mammals, such as mammoths, or on human remains and artefacts, much information on smaller mammals was obtained; this formed the basis as long ago as 1926 for a large (though uncompleted) monograph by Hinton (*Monograph of Voles and Lemmings (Microtinae) Living and Extinct*, British Museum, (Natural History), London). While this early work established Quaternary biology as a science, it suffered, as pioneering work inevitably must, from being too early. The fossil mammals were subjected to an extremely typological classification, with names founded on extreme variants, and more normal intermediates left unnamed. The very complex nature of

ALTHOUGH it was the first nuclear process studied by Rutherford, alpha decay is still not properly understood. A large number of alpha decay rates have now been measured for heavy nuclei, and these depend basically on two factors, a nuclear structure factor that gives the probability that there is an alpha particle in the nuclear surface 'waiting to get out', and a penetration factor that gives the probability that it will be able to tunnel quantum-mechanically through the barrier and so escape from the nucleus.

Ever since Gamow first applied quantum mechanics to the nucleus, it has been known that the penetration probability depends very critically on the height and width of the potential barrier through which the alpha particle has to tunnel, and hence on the energy of the emitted alpha particle. This is why the alpha decay halflives vary from a very small fraction of a second to many thousands of years, while the corresponding alpha energies vary by less than an order of magnitude.

This simple theory was very successful in accounting for the relative alpha decay rates of a large number of radioactive nuclei, but the absolute values were much less certain, due to the lack of knowledge of the nuclear structure and of the potential barrier. Using the best available nuclear structure information, there was usually a factor of a thousand between the measured and calculated decay rates and it was generally considered that this large factor was still within the uncertainties of the potentials.

This point has now been carefully checked by De Vries at Rochester and Lilley and Franey at Minnesota (*Phys. Rev. Lett.*, **37**, 481; 1976). They

Absolute alpha decay rates

from P. E. Hodgson

studied the interaction of alpha particles with ^{208}Pb and ^{209}Bi and fitted the experimental data for elastic scattering at 22 MeV and the reaction cross section from 17 to 24 MeV by a series of optical model potentials. The reaction cross sections are known accurately since they are the sum of the (α,n), $(\alpha,2n)$ and (α,γ) cross sections, all of which can be measured accurately. No other reactions are energetically possible.

They found that this data imposes tight restrictions on the optical potentials, so that an acceptable fit can only be obtained with parameters constrained within narrow limits. The penetrabilities calculated from these potentials vary somewhat, but far less than was previously thought. This makes it possible to calculate accurate absolute values of the quantity called the reduced alpha width γ^2 that contain the nuclear structure information alone. It is found that these values are still about a thousand times greater than those calculated from the shell model. For example, for ^{210}Po, the value of γ^2_α found from the measured alpha decay rate and the calculated penetrability is 0.88 $^{+4.4}_{-0.19}$, whereas the value calculated from the shell model by Harada is only $(0.31$ to $3.3) \times 10^{-3}$. Results for other nuclei are similar.

This is a serious discrepancy and shows the need for much more sophisticated nuclear structure calculations, including more configuration mixing and the renormalisation required by antisymmetrisation. A thousand times more alpha particles are emitted than would be expected from existing shell model calculations, so it may well be that this is due to substantial clustering of alpha particles on the nuclear surface that cannot yet be described by the shell model. ☐

---

the climatic fluctuations was not appreciated either (indeed Hinton was a monoglacialist, and so assigned faunas either to "the" cold period or to the preceeding warm period), with the result that much ecological and stratigraphical information was overlooked or lost.

Biological aspects of Pleistocene study have been revolutionised first by pollen analysis and more recently by the study of insect, especially beetle, faunas; physical aspects of study have added absolute chronologies (from radiocarbon and other dating techniques) and absolute temperature calibration (from oxygen isotope ratios). In this surge of knowledge, Pleistocene mammals have, at least in Britain, been left far behind; Zeuner's book (*The Pleistocene Period*, Hutchinson, 1944) contained a chapter of 30 pages on mammals, but only four single-line entries on pollen analysis, whereas West (*Pleistocene Geology and Biology*, Longman, 1968), has 32 pages on pollen stratigraphy but only six on mammals.

Clearly the time was ripe for restudy of British Pleistocene mammals, not only in their own right but also to integrate them into the newer framework of Quaternary chronology. Some significant signs of such restudy are now available. One is Stuart's review relating all available vertebrate occurrences to the pollen stratigraphy of Britain (*Biol. Rev.*, **49**, 225–266; 1974). this involved new collecting from sites where information on pollen was available or obtainable as well as a re-examination of a scattered and often obsolete literature. Another equally valuable review of a different type is Maglio's paper on the evolution of the elephants (*Trans. Am. phil. Soc.*, **63**, 1–149; 1973). Because they are so conspicuous, fossil elephants, or at least their molars, have played an important part in stratigraphy, but their taxonomy has been extremely muddled.

Perhaps the most important such contribution has just been published by Sutcliffe and Kowalski (*Pleistocene Rodents of the British Isles, Bull Br. Mus. (nat. Hist.) Geol.* **27**, 31–147; 1976). This account is important in a number of respects. For a start, the rodents are, and have been throughout the Pleistocene, the most numerous mammals; they are therefore the most abundant in cave deposits, and so potentially the most useful archaeologically or stratigraphically, and they are arguably the most important ecologically. Their potential has however been largely unrealised, partly perhaps because archaeologists have tended to ignore them, but largely because, as a result of the early studies, they were in a taxonomically unsatisfactory state and therefore unreliable stratigraphically. This review should at least resolve these last obstructions. The literature records are thoroughly reviewed, and their stratigraphical assignments reassessed. The taxonomy is also reviewed, so that it is now much clearer just how many distinct species were present in the Pleistocene. The dubious taxa erected by Hinton, among others, are thoroughly scrutinised, and many are relegated to synonymy. Of particular importance is the cautious reassessment of *Microtus* species, especially *M. arvalis*. This vole has a rather southern distribution in Europe, being absent from Scandinavia and, except for Orkney and Guernsey, from Britain. The occurrence of fossil remains attributed to it, however (often as *M. corneri*) have led to suggestions that it was an early postglacial immigrant, since isolated as a relict in Orkney. Not only is this inherently unlikely on ecological grounds (human introduction being more likely an explanation) but, as this review makes clear, the supposed fossil occurrences are very doubtful indeed. The

review also reveals however many very real problems which require further study or perhaps further material. For example, we do not know for certain when lemmings disappeared from Britain nor whether, as the evidence suggests, the high Arctic collared lemming, *Dicrostonyx torquatus*, survived later than the more southerly *Lemmus lemmus*.

More important, however, than this sort of query which the review poses is the framework which it provides for evolutionary studies. G. R. Coope (personal communication) has averred that beetles, because of their mobility, provide a better indicator of past climates than plants, but that their reliability for this depends on their evident morphological stability and presumed ecological stability throughout the Pleistocene. Plants also seem to have evolved little. The rodents, however, share the mobility of beetles, but at the same time demonstrate considerable evolutionary flexibility. Their rates of evolution and the relationship of these to ecological changes are aspects which should begin to attract attention.

Cosmic rays at Leeds

from a Correspondent

> The fifth European Cosmic Ray Symposium was held at Leeds on September 14–17, 1976.

COSMIC ray studies still have a lot to offer the nuclear physicist. That at the very least was clear from the discussions at the symposium. The energies available with cosmic ray particles (up to $\gtrsim 10^{20}$ eV) still far exceed the best accelerators. Thus effects such as high transverse momentum and increasing cross sections for hadron interactions that are perhaps beginning to appear at the highest machine energies should be clearly observable from cosmic ray studies. If, as accelerator work initially seemed to indicate, Feynman scaling theory holds then it should become very evident at these high energies.

Experimentally, problems arise in studying high energy cosmic rays because of their inacessibility and very low flux. The high energy primary particles reaching the Earth interact in the atmosphere causing a cascade of secondary particles to reach sea-level in the form of an Extensive Air Shower (EAS). Since the low primary flux makes direct collection virtually impossible these EASs are the only convenient means of investigating the nature and properties of the high energy particles.

A major topic at the Leeds symposium was the attempt to relate the experimentally measured properties of the EAS to theoretical predictions based on cascade calculations assuming both a nuclear physics model and a particular mass composition spectrum for the primary particles. High transverse momentum phenomena in nuclear interactions (diverging from average CKP behaviour) have been a topic of discussion at cosmic ray conferences for many years, and now positive evidence is also appearing from accelerators. Controversy still reigns, however, as to the magnitude of the effect or indeed whether the observed events could be just the expected high momentum tail from the CKP distribution.

The scaling theory of nuclear interactions came in for a lot of hammering. Evidence is accumulating from EAS research against 'scaling' being operative at high energies. Here a problem in interpretation is the uncertainty in the mass composition of the primary cosmic ray particle initiating the EAS. Assuming the established composition at low energies (~80% protons) then 'scaling' appears to be incompatible with experimental EAS data. However if predominantly iron primaries are assumed to occur ~10^{17} eV the 'scaling' theory can perhaps be rescued. An additional concern, pointed out at the symposium, was the as yet inadequate treatment in the model calculations of extreme fluctuation effects coupled with the steeply falling primary energy spectrum. Rigorous calculations may well make 'scaling' more acceptable. In passing it should be noted that recent results from Fermilab and Stanford on deep inelastic scattering also show departures from 'scaling'.

The most exciting experimental work in EAS studies discussed at the symposium was reported by K. E. Turver and colleagues from the University of Durham. This group have very carefully measured the Cerenkov radiation produced in the atmosphere by EAS. These observations were recorded at the Haverah Park detector array, North Yorkshire, from EAS of primary energy >10^{17} eV. Although such atmospheric Cerenkov radiation has been investigated previously the advance by Turver's group was achieved by making use of a well-spaced array of eight photomultiplier detectors and correlating their responses. By analysing the pulse shape from the different detectors the researchers claim to be able to pinpoint the EAS development with a considerable degree of accuracy. It is fairly early days in their investigations but the technique looks very promising. The main problem at the North Yorkshire moors array is the available operation time as clear dark

nights are required—only 100 hours was achieved last winter. However, if this technique is established at Haverah Park, in close collaboration with the particle detector array there, then it should be possible to set up such an air Cerenkov array independently in a more favourable climate.

The origin and mass composition of the high energy primary cosmic rays still remain the key astrophysical questions to be answered. The extragalactic *versus* galactic origin controversy continues with almost equal support on both sides. Until recently it seemed that cosmic rays even at the highest energies appeared to reach the Earth equally from all directions. However, as the statistics of the really high energy events ($\gtrsim 10^{18}$ eV) built up in recent years there does appear to be some evidence for a small degree of anisotropy in right ascension. A. M. T. Pollock and A. A. Watson (University of Leeds) presented data on the arrival direction of primary particles of energy 10^{17}–10^{18} eV. Some 45,000 EASs were subjected to harmonic analysis in right ascension. A significant amplitude (0.1% chance probability) occurs in the direction of $251(\pm 15)^\circ$ RA. Evidence from the same group at higher energies (>10^{18} eV) is not so conclusive. There seems to be a change of phase with increasing energy but it is regarded as significant that the two highest energy events ($\gtrsim 10^{20}$ eV) come from close to the North Galactic Pole. D. D. Krasilnikov (Institute of Cosmophysical Research, Yakutsk, USSR) has plotted the arrival directions of the total world accumulation of 67 reported events greater than 4×10^{19} eV. An equatorial region in the galactic coordinate system seems to be practically devoid of events. Krasilnikov concludes that this can be interpreted as the result of screening by magnetic fields of an isotropic flux of the particles coming from outside the Galaxy radiodisk. If these particles were of galactic origin they would be required to be heavy nuclei from a powerful source in the centre or behind the centre of the Galaxy and influenced by a highly extensive radio halo with a very specific regular magnetic field structure. It is more likely that they are of extragalactic origin. Attempts to correlate arrival directions with pulsars have proved negative.

This symposium represented a special occasion in that for the first time the lower energy cosmic ray work (modulation section) was discussed at the same meeting as the high energy and EAS work. Usually two separate symposia are held at different venues. The amalgamation was in honour of Professor J. G. Wilson whose life-long interest in cosmic rays has spanned both branches of the research field. John Wilson is this year retiring from

the Cavendish Chair of Physics at the University of Leeds which he has held since 1952. His research in cosmic rays started under C. T. R. Wilson and he became a prominent member of P. M. S. Blackett's group at Manchester after the Second World War. Latterly he has been responsible for setting up and developing the EAS detector array at Haverah Park. He plans to continue his interest in the field during his retirement.

J. G. Wilson presented a paper dealing with the energy spectrum of cosmic rays at energies $\gtrsim 10^{17}$ eV. Evidence continues to mount in support of a flattening of the spectrum above 10^{19} eV. There appears to be no cut-off at this energy arising, as predicted, from interaction with the supposed universal 3 K photon flux. This inconsistency still remains a problem as the arrival direction analysis does seem to suggest an extragalactic origin for these very high energy cosmic rays.

In general then cosmic ray research still appears to be a hive of activity with plenty of promise. However, progress is inevitably slow, perhaps reflecting the difficulties of both technique and interpretation. ☐

Efficient bumblebees are almost specialists

from John Krebs

THE familiar sight of bumblebees gathering pollen and nectar from wild flowers is the basis of a recent study by B. Heinrich (*Ecol. Monogr.*, **46**, 105; 1976), in which he analysed the foraging behaviour of individually marked worker bees of the genus *Bombus*. The bee uses different techniques to collect pollen and nectar from different plant species, for example it collects pollen from dogwood by pressing its body on the flat inflorescence, while on the cranberry it hangs upside down and shakes the pollen onto its body. The bees in Heinrich's study area preferred certain flower species over others: *Chelone* being the most favoured and *Solidago* the least. In fact the rank order of preference (measured by the number of bees per flower) corresponded exactly to the rank order of potential nectar yield from the various species—I will return to this point later. While this picture applies to the whole bee population, each individual bee specialises on a particular plant species (its 'major') and occasionally visits one or two other species ('minors'): the overall distribution of foraging effort by the bees is the sum of many specialists on different plants.

Specialisation is not purely a result of attachment to one particular site, nor is it temporary; many workers probably retain the same 'major' throughout their life of four to six weeks. The 'minors' of individual bees are also constant, but Heinrich found that he could induce workers to adjust their preference by adding sugar droplets to a 'minor' in their repertoire, which then became the 'major', showing that the choice of a 'major' is related to how profitable different plants are. The benefit to a bee of specialising was revealed in an experiment in which Heinrich compared the efficiency of experienced and naive bees in extracting nectar from monkshood, which is unusual in having its nectar hidden in two modified petals. The naive bees, which had foraged on other flowers but not monkshood, had difficulty in finding and extracting the nectar while the specialists did not. This and other observations suggested that a non-specialist bee would be rather unsuccessful in competing for nectar and pollen with a specialist.

Heinrich's results pose two intriguing questions: Why do all bees not major on the most profitable flower species? And why do individuals maintain minors in their repertoire? The answer to the first question is straightforward. As I have mentioned, the bee population as a whole distributed its foraging effort according to the order of profitability of the various flowers, so that the commonest major is the top ranking nectar source, the next commonest major the second ranking plant and so on. It also turns out that after the foragers have exploited an area, all the different plants contain about the same amount of left-over nectar—they are all reduced to the same level of profitability. This means that the lower nectar content of poor quality flowers is (more or less) exactly compensated for by the fact that more bees compete for nectar in the rich flowers. (This pattern of harvesting, which has also been observed in birds, is predicted by theoretical models describing how a maximally efficient forager ought to behave, but more of that another time.)

The question of why bees maintain minors is more difficult, but G. Oster and B. Heinrich (*Ecol. Monogr.*, **46**, 129; 1976) have developed a model to offer a tentative explanation. Their argument goes like this: if there is an array of flowers giving different quantities of nectar per unit effort, an efficient worker with perfect knowledge should forage purely in the most profitable flowers. When the bee has no previous knowledge, it has to sample the flowers to estimate their profitabilities and then adopt the "pure strategy" of foraging in the best

flowers. But suppose Nature is awkward, and the different flower types continually change ranks, what should the bee do? In the extreme case, when Nature obeys Murphy's Law and what the bee thinks is best immediately becomes the worst, a "mixed strategy" is best because it insures against a sudden change. Assuming that Nature is perverse but not too perverse, the bee's best strategy lies somewhere between mixed and pure: majoring with one or two minors. ☐

Photobiology

from R. P. F. Gregory

> The Seventh International Congress on Photobiology was held in Rome on August 25–September 3, 1976.

WHAT advances stand out after four years' study of photobiology? G. Porter (Royal Institution, London) gave one answer in terms of picosecond kinetics. The primary processes of light-absorption by a pigment and its re-emission in fluorescence can now be studied at times approaching a few picoseconds using the streak camera. (The absolute theoretical barrier was set by the Uncertainty Principle in the region of 0.5 ps.) Both by advances in the understanding of the behaviour of excited states of pigments and the application of ultrashort pulsed laser spectroscopy, models have been produced of the operation at the nanosecond timescale of three photobiological pigments. M. Ottolenghi (Hebrew University, Jerusalem) described the interconversions of rhodopsin, bathorhodopsin and isorhodopsin in terms of the energy level diagram and was able to account for the observed quantum yield. Remarkably similar behaviour was reported for the analogous pigment bacteriorhodopsin from the typical phototroph *Halobacterium* (R. H. Lozier and colleagues, Ames Research Center, California). The phototransformations of phytochrome, preceding the appearance of the Pr and Pfr forms, are also in the model stage (R. E. Kendrick, University of Newcastle-upon-Tyne). Outside the formal sessions it was apparent that the problems of pigment organisation and the spectroscopic methods presently available for their investigation were common to these topics and also to the study of chlorophyll, both in membranes and in pigment-protein complexes. At this level Photobiology very clearly exists as a discipline.

The importance of flavins or flavoproteins in many responses of organisms to light is becoming apparent, and the much debated alternative, carotene, is on the retreat, in such examples as the flagellar response of *Euglena*, and the development of the coleoptile of oat seedlings. Flavoproteins also appear to provide an explanation for the various 'blue-light effects' in mitochondria, *Neurospora* and the alga *Protosiphon botryoides*. In several cases there is clear evidence that the flavin is coupled to an electron transport system, such as a *b*-cytochrome or plastocyanin. In these examples the metabolic links between the action of the pigments and the observed effects on the organisms were relatively obscure; however, in photosynthesis there have been impressive developments in metabolism. These cover both the chloroplast–cytoplasm relationship of the normal (C3) system and the agriculturally-wasteful process of photorespiration. H. R. Bolhar-Nordenkampf (The University, Vienna) described techniques of measuring photosynthesis and photorespiration in crop leaves, from which the behaviour and future yield of the crop could be assessed. The possibility of photorespiration being an essential detoxification system for the various oxide radicals continues to be discussed.

The subject very clearly divides between the above 'natural, positive' aspects, and the adventitious and negative effects of light, particularly ultraviolet. Although there is considerable data on the effects of ultraviolet on proteins and nucleic acids, the carcinogenic action on human skin could not be simply explained. A more satisfactory molecular explanation could be claimed concerning the success in treating certain skin diseases such as psoriasis and mycosis fungoides with psoralens (which bind to DNA) and UV-A light (M. A. Pathak, Harvard Medical School). Not only ultraviolet, but visible light was clearly shown by J. Marshall (Institute of Ophthalmology, University of London) to lead to striking degradation of retinal cones in animals and people subjected to artificially extended daylength.

The contribution of photobiology to economic problems occupied much attention, in that in principle solar energy remains the one large source of energy available for immediate use. Biological conversion was discussed by D. O. Hall (King's College, London) who pointed out that in many areas existing knowledge and technology could provide not only increased food crops but materials such as ethanol and glycerol at competitive prices. In several cases it had been shown that producing crops under cover in large areas with varied CO_2 levels not only relieves losses by photorespiration, but also increases nitrogen fixation and water economy. W. J. Oswald (University of California, Berkeley) is of course unchallengeable in his presentation of algal sewage-farming at a profit. A. A. Krasnovsky (Academy of Sciences, Moscow) and others set out possible photoconversion systems based on isolated pigments or stabilised membrane systems, provided with enzyme systems, for the production of hydrogen. It remained doubtful, however, whether simulated photosynthesis for the production of, essentially, heat would be competitive with existing 'solar panels' for heating (and refrigerating). The discussion of this topic (as Porter had the opportunity to point out in the Farrington-Daniel memorial lecture) has had a phenomenal growth rate in the past four years, and raised Photobiology to the status of a political issue. □

Sicily as the sum of parts

from Peter J. Smith

THE notion that Sicily straddles lithospheric plates is by now a familiar one. The crystalline massif forming the extreme northeast of the island is a continuation of the Calabrian metamorphic belt and thus linked geologically with Europe. The Ragusa carbonate platform in the extreme southeast, on the other hand, is an extension of the Sahara platform and thus linked geologically with Africa. The boundary between the African and European plates (see McKenzie, *Geophys. J.*, **30**, 109; 1972) probably runs along the northern edge of Sicily, except in the east where it lies south of the massif.

This interpretation places the re-sedimentation basin and nappes which form the western and central parts of the island firmly on the African plate. Indeed, Barberi *et al.* (*Earth planet. Sci. Lett.*, **22**, 123; 1974) were apparently able to confirm this when they showed palaeomagnetically that, the crystalline northeast apart, Sicily has been part of the African plate since the Cretaceous. But as might be expected from Sicily's marginal position, things may not be that simple. Caire (in *Gravity and Tectonics*, Wiley, 1973), for example, has suggested that there may have been a second intra-island plate boundary isolating the Ragusa platform—a possibility apparently not excluded by the work of Barberi and his colleagues who analysed rocks only from the extreme east.

To test this idea, Schult (*Earth planet. Sci. Lett.*, **31**, 454; 1976) has now carried out a palaeomagnetic study of Upper Cretaceous and Middle Jurassic volcanic rocks from the west of Sicily. The two poles thus obtained are not only significantly different from those of comparable ages for Europe (as expected) but are even further removed from those for Africa and the Ragusa platform. Since the Upper Cretaceous, western–central Sicily has apparently rotated clockwise by about 90° with respect to southeastern Sicily (and hence with respect to Africa) and by about 60° with respect to stable Europe.

Schult admits that the margin of error on his results is larger than one would wish; but taken at face value the new poles confirm Caire's proposal that western–central Sicily and the Ragusa platform once behaved as, or as part of, separate crustal blocks. And implicit in that confirmation is western–central Sicily's unique sense of rotation. All other known crustal block rotations in the central Mediterranean were apparently anti-clockwise. □

Stratospheric aerosols and climatic change

Betty Baldwin, James B. Pollack, Audrey Summers & Owen B. Toon

Space Science Division, NASA–Ames Research Center, Moffett Field, California 94035

Carl Sagan

Laboratory for Planetary Studies, Cornell University, Ithaca, New York 14853

Warren Van Camp

Informatics, Inc., Palo Alto, California

Global heat balance calculations imply that stratospheric aerosols, generated by volcanic explosions, have made important contributions to some observed climatic changes but that such aerosols generated by supersonic transports and Space Shuttles are unlikely in the next few decades to have a significant climatic impact.

THE stratosphere contains a layer of submicron-sized particles, centred at an altitude of $\sim$ 20 km and extending from the tropopause to an altitude of $\sim$ 30 km (ref. 1). Usually, the particles of this layer are made primarily of a concentrated sulphuric acid solution[2,3], which is generated *in situ* from sulphur-containing gases that undergo a series of oxidation and hydration reactions[1]. At present, volcanic explosions are very important sources of these aerosols because of the sulphurous gases they inject into the stratosphere[4]. Volcanic explosions also introduce silicate particles into the stratosphere[4,5]. Because the gas–particle conversion has a time constant $\sim$ 1 yr (ref. 1), silicates are the dominant aerosol species in the first few months following a volcanic explosion[5], but H_2SO_4 dominates for the next few years[4]. A future source of stratospheric aerosols may be from flight through the stratosphere. The effluent from supersonic transports (SSTs) includes sulphur-containing gases, which will be converted to H_2SO_4, while the exhaust from Space Shuttles contain tiny aluminium oxide particles[1,6,7].

It is important to understand the climatic changes that might be produced by stratospheric aerosols. One variable useful in characterising the climate is the globally-averaged surface temperature, T, which depends on the global heat balance between the amount of solar energy absorbed by the entire Earth and the amount of thermal radiation emitted to space. Stratospheric aerosols scatter and absorb solar radiation and interact with and produce thermal radiation. Changes in their number will thus cause a temporary imbalance between the solar energy absorbed and the thermal radiation emitted to space and necessitate an adjustment in T to restore the global heat balance. We perform here accurate radiative transfer calculations to estimate the sensitivity of the climate to changes in the number of stratospheric aerosols. The results, when combined with observed changes in the level of volcanic activity, permit us to assess volcanism as a cause for past climatic changes. Calibrating by these findings, we calculate the climatic impact of future vehicular traffic through the stratosphere.

The model

We here summarise our radiative transfer calculations of T, specify the sources of our model's parameters, discuss factors not included in our calculations, and, where possible, introduce approximate corrections for these factors. It is not possible to evaluate the full climatic impact of changes in the number of stratospheric aerosols; but because the direct effect of these particles is radiative, our calculations provide a useful measure of the sensitivity of T to such changes.

For a specified model atmosphere, including a vertical profile of the aerosols, we determine the value of T that leads to global heat balance. Climatic change is measured by ΔT, the difference in T between the perturbed and unperturbed state. An accurate method, based on the doubling principle[8,9], was used to solve the multiple scattering problem for unpolarised light and so determine the amount of solar energy absorbed by the Earth. The thermal radiation emitted to space was found by numerical evaluation of the formal solution of the equation of radiative transfer[10]. For the solar calculations, account was taken of the absorption and scattering from both gases and aerosols. Because the single scattering albedo of stratospheric aerosols is small in the thermal infrared[11], scattering was neglected in the thermal calculations, but the opacity of both gases and aerosols was included. While no allowance was made for diurnal, latitudinal or seasonal variations in the model parameters, we did include vertical inhomogeneities. Also, tropospheric water clouds are present over 50% of the globe. A more detailed discussion is given elsewhere[4,7,8].

An increase in the amount of stratospheric aerosol can lead to either a warming or cooling of the Earth. Our radiative transfer calculations, as well as those of others[12], indicate that the sign and magnitude of ΔT depends critically on the real and imaginary parts of the refractive indices of the added particles, their size distribution, and the surface albedo. We use the measured refractive indices for materials constituting the aerosols of interest[13-15] and size distributions based upon available measurements[11]. Finally, we use a value of 0.1 for the surface albedo[16].

The increase of the optical depth of the stratosphere, $\Delta \tau$, caused by the addition of particles has a strong effect on the magnitude but not the sign of ΔT. This parameter is proportional to the number of added particles which are large enough to interact efficiently with light. Figure 1 illustrates the variations of $\Delta \tau$ over the past century, as determined from observations of the amount of unscattered sunlight and starlight transmitted by the atmosphere[4], and many of the observed
Fig. 1 Optical depth perturbations of the atmosphere at a wavelength of 0.55 μm as a function of time, and volcanic explosions that Lamb[25] has judged to have injected significant quantities of dust into the stratosphere. The dust veil index (DVI) is Lamb's assessment of the importance of an eruption. The larger perturbation in 1963 is a Southern Hemisphere value, and the smaller a Northern Hemisphere value. The error bar in 1912 represents a measurement at one location of a single day's perturbation and a one-month average. The solid curve is an average of monthly mean optical depths at several locations. Note the phase lag between the times of eruption and peak optical depths—partly because of the slow transport of dust from the point of injection into the stratosphere and partly because of the slow photochemical conversion of sulphur-containing gases to sulphuric acid aerosols, as is observed directly[37].

changes in $\Delta\tau$ can be associated with major volcanic events. We estimated $\Delta\tau$ for other times from less direct information, as indicated in the footnotes to Tables 1 and 2. In making these latter estimates, we have neglected any variation in the stratospheric residence times of the aerosols, which could result from changes in the stratospheric temperatures.

Our calculations neglect several feedback mechanisms that might augment the temperature changes (alterations of the snow and ice cover), retard these changes (an alteration in the dynamical heat transport), or has either effect (variation in cloudiness). Current climate models that include the first two of these feedback mechanisms suggest they cause an amplification by a factor of 4 in ΔT for transitions from interglacial to glacial conditions[17,18]. Since 10^3–10^4 yr are required to establish the great continental ice sheets[19,20], we multiply our results by this factor when dealing with changes on time scales $> 10^3$ yr, and use a smaller factor for time scales as short as a few hundred years[21].

Our calculations are also limited to the steady state, in which perturbation persists for a much longer period, P, than the response time of the land–atmosphere–ocean system, t. When dealing with time scales of a few months or less, when $P < t$ for both the troposphere and ocean[4], we hold the tropospheric and ground temperatures constant and consider only temperature changes in the stratosphere. For somewhat longer time scales (still < 4 yr) $P > t$ for the troposphere, but $< t$ for the mixed layer of the oceans[4]. In this case we multiply[4] our calculated value of ΔT by $P/2t$.

Volcanic activity as an agent for climatic change

Using this model, we have calculated ΔT for past, observed changes in the level of explosive volcanism and have compared the results with contemporaneous observations of ΔT. Table 1

summarises the results. The first two rows refer to the effects of single volcanic explosions, while the remaining rows refer to the effects of multiple volcanic explosions. The rows are also ordered according to the duration of the climatic change; the top row refers to the shortest time interval.

Comparison between the observed and predicted values for the first two rows of Table 1 provides a test of the validity of our model calculations. The calculated increase in the stratospheric heating rate agrees well with the increase observed during the first few months after the Mt Agung eruption. Also, the calculated decrease in the average surface temperature for the 2-yr period following an eruption is in accord with the observed decrease to within their mutual uncertainties. The net effect of volcanic explosions is to cause a temporary cooling of the Earth.

Rows 3 and 4 of Table 1 permit an assessment of the contribution of volcanic activity to the ΔT observed over the past century. This comparison is shown in greater detail in Fig. 2, where we have also indicated the ΔT expected from the observed increase in the CO_2 content of the atmosphere, coming primarily from the burning of fossil fuels[22–24]. We have set the reference point of the temperature scale at 1885. The increase in T from the end of the nineteenth century until 1940, shown by the theoretical volcanic dust curve, arises from the declining level of volcanic activity over this period. Thus, the temperature was depressed during the early part of this period when there was much volcanic activity, but no such depression occurred during the later, volcanically quiescent times.

Figure 2 and Table 1 suggest that changes in the level of volcanic activity have made a significant contribution to the increase in surface temperature from the end of the nineteenth century to 1940, and a less significant contribution to the decline in temperature from 1940 to the present. Because we did not include possibly important feedback effects, such as variations in cloudiness, we cannot make a precise estimate

Table 1 Comparison between observed temperature changes and those expected from volcanic aerosols

Comparison		Characteristic of variable being compared			Model parameters				Comments
Observed value	Predicted value	Variable	Place	Time period	Aerosol species	$\Delta\tau$	F_1*	F_2†	
0.1 (ref. 34)	0.1‡	Atmospheric heating rate§	Southern Hemisphere, lower stratosphere	First several months after the Mt Agung eruption in 1963	silicate dust	0.1‖	—	—	The main source of the heating is absorption of outward-directed thermal radiation by the added aerosols rather than their absorption of solar radiation[4].
−0.3 (ref. 26)	−0.2	Mean surface temperature change, $\Delta T'$¶	Northern Hemisphere	Epochal average for a 2-yr period after an eruption	sulphuric acid	0 as against 0.1‖	0.25	1	The observed value was obtained by averaging the results of 13 separate events. This averaged value is statistically significant at the 1 % level.
+0.6 (ref. 35)	+0.5	Mean surface temperature change, ΔT¶	Northern Hemisphere	1880–1890 as against 1935–1945	sulphuric acid	0.07 as against 0'‖	1	1	
−0.3 (ref. 35)	−0.15	Mean surface temperature change, ΔT¶	Northern Hemisphere	1935–1945 as against 1965–1970	sulphuric acid	0 as against 0.02‖	1	1	The agreement between the predicted and observed ΔT from 1940 to 1970 is worse than is apparent from this Table. See Fig. 2.
∼+0.5 (refs 25, 33) +0.3–+0.6		Mean surface temperature change, ΔT¶	Northern Hemisphere	1450–1915 (Little Ice Age) as against 1935–1945	sulphuric acid	0.03** as against 0	1	1— 2	The full ice–snow albedo feedback will not be realised since there was insufficient time to build large continental ice sheet. However, observations suggest that some increase in snow cover may have occurred during the Little Ice Age[21].
+4 (refs 29, 33) +0.7–+7		Mean surface temperature change, ΔT¶	Both hemispheres	12,000– 25,000 BP as against now	sulphuric acid	0.02– 0.2†† as against 0	1	4	12,000–25,000 BP was the coldest part of the last ice age.

*Correction factor for the finite response time of the atmosphere–ocean–land system. A response time of 4 yr was used to calculate F_1 for the second row. This value was derived from the amount of mass in the mixed layer of the ocean[4,33].

†Correction factor for feedback from a change in ice and snow cover and in the atmospheric dynamics[17,18]. This correction factor is poorly known.

‡The tropospheric temperature was held constant because the response time of the troposphere is several months[4,36].

§In units of K d^{-1}.

‖Found from Fig. 1.

¶In K. ΔT as given in the first and second columns of the table is the difference in temperature between the second and first time period of the fifth column. For example, the observed value of +0.6 given in the third row means T increased by 0.6 K from 1880–90 to 1935–45.

**The $\Delta\tau$ value for the Little Ice Age was found from Lamb's[25] dust veil indices (DVI). The DVI for this period are based primarily on estimates of the amount of mass ejected by volcanic events. We assumed that DVI is proportional to $\Delta\tau$ and found the constant of proportionality from data on both quantities for the period 1880–1915 (ref. 4). The $\Delta\tau$ given in Table 1 for the Little Ice Age is thus only a rough estimate.

††The values of $\Delta\tau$ were derived from the sulphate concentration found in ice cores[28]. In deriving these values we assumed a residence time of 1 yr for the H_2SO_4 particles in the atmosphere, values of 30 cm yr^{-1} and 15 cm yr^{-1} for snow accumulation rates in Greenland and Antarctica, respectively[29,28], and the present 'normal' size distribution function of the stratospheric aerosols. The lower value of $\Delta\tau$ in the Table is a value found from the sulphate concentration for the Antarctic cores, while the higher value pertains to the sulphate concentration of the Greenland cores.

of these contributions. CO_2 was less important than volcanic aerosols in causing the temperature increase from the end of the nineteenth century until 1940. The relative ranking of these two effects, however, may well reverse itself during the next several decades and the Earth could experience a net warming over this period if no other factors intervene (such as man-made dust[16]).

During the period from ∼ 1450 to 1915, the Earth was enveloped in the 'Little Ice Age'. Mountain glaciers and sea ice were more extensive than now, Northern Hemisphere temperatures were ∼ 0.5 K colder than those for 1935–1945, and volcanic explosions were common[25–27]. The volcanic activity between 1880 and 1905 shown in Fig. 1 is typical of the Little Ice Age in terms of number and magnitude of eruptions[25]. The results of Table 1 suggest that the high level of volcanic activity during the Little Ice Age had an important role in causing the low temperatures of this period.

Ice cores from Greenland and Antarctica contain information on both aerosol content and temperature[28,29] that allow us to assess the importance of volcanic activity in generating and sustaining the last major ice age, the Wisconsin, which occurred

from ∼ 75,000 BP to 12,000 BP. Because the residence time of submicron-sized aerosols in the stratosphere is ∼ 1 yr, aerosols produced by a volcanic explosion are distributed uniformly over at least the hemisphere of the explosion, except for a short period immediately following the explosion[4,12]. Thus, aerosol-derived material found in ice cores provides a useful measure of the aerosol content of the stratosphere at the time the ice was layed down. Studies of the anion content of ice cores[28] show that their sulphate content was distinctly higher than its present value and reached a maximum value during the 13,000-yr period at the end of the Wisconsin, a time when T had its minimum value. The sulphate enhancement was significantly greater for the Greenland cores than for the Antarctic cores. Sulphate also occurs in tropospheric aerosols, so an increase could result from non-volcanic sources. Assuming that the enhancement in sulphate content is caused by volcanic aerosols, we obtain estimates of ΔT for the later part of the Wisconsin ice age (Table 1) and find that volcanic aerosols could have made a significant contribution to the observed low temperatures.

Table 2 Estimated effect of vehicles flying through the stratosphere

Aerosol source	Time frame	$\Delta\tau^*$,†	ΔT‡
SSTs and other high-flying aircraft	1990 nominal	4.9×10^{-4}	5×10^{-3}
	1990 maximum	8.9×10^{-4}	9×10^{-3}
	2000 nominal	1.1×10^{-4}	1×10^{-3}
	2000 maximum	3.3×10^{-4}	3×10^{-3}
Space Shuttles	1990	3.3×10^{-5}	1.5×10^{-4}

*The Space Shuttle and SST perturbations are estimates for the Northern Hemisphere. Southern Hemisphere values should be 3/7 as large. SSTs are responsible for 70% of the $\Delta\tau$ values.

†The $\Delta\tau$ values were obtained from estimates of the number of vehicles, their emission characteristics, and properties of the stratosphere[4,3,3].

‡Temperatures (K).

Further support for this proposition comes from the discovery[29] of ~ 2,000 volcanic dust bands and ~ 25 volcanic ash bands in Antarctic ice cores. The small particle sizes ($\leq 5 \mu m$) in the dust bands suggest that the dust originated from distant sources. The observed onset of sustained volcanic activity occurred simultaneously with observed strong cooling, the lowest temperature accompanied the greatest dust fall-out, and a cessation of dust bands and an increase in temperature were contemporaneous[29]. Finally, the average mass concentration of volcanic dust during the last part of the ice age implies the presence of a comparable amount of volcanic sulphate. This is consistent with the observed sulphate enhancement for the period.

While volcanic activity appears to have contributed to an intensification of the Wisconsin ice age during its later stages, the available evidence suggests that it had little to do with the early and middle portions of this ice age. Few dust bands occur in the Antarctic cores[29] for this period and little enhancement is seen in the sulphate content of the cores from both hemispheres[30].

At times earlier than the Wisconsin ice age, there are a few data that hint at a significant volcanic role in causing climatic change. A dramatic cooling known as the '90,000-yr BP' event has been detected both in polar cores and in sea cores. In the sea cores it was closely associated with a volcanic ash layer[30] and in the polar cores there was an order of magnitude more dust (not necessarily volcanic) during the event than at present[31]. Finally, studies of the number of volcanic ash layers in deep-sea
Fig. 2 Observed Northern Hemisphere surface temperature changes[25] (——) and theoretical estimates of the temperature changes from observed CO_2 and volcanic dust variations (·—·—·). CO_2 alone is the solid, steadily rising curve, and volcanic dust alone is – – – –. To estimate the volcanic temperature changes we use the optical depth data in Fig 1 averaged over 10-yr periods and only consider the years 1884–1892, 1903–1904, 1907–1908, 1912–1914 and 1963–1970 to have any volcanic dust present. The 10-yr averaging period was chosen to allow for response times in the Earth's climate system. An even better fit, especially between 1900 and 1920, could be obtained by other choices of averaging period.

cores indicate that the worldwide level of volcanic activity during the Quaternary, the time of the ice ages, was much greater than during the previous 20×10^6 yr (ref. 32).

In summary, volcanic aerosols seem to have made important contributions to climatic changes in the past, but apparently do not offer a complete explanation of all recorded changes.

Possible climatic impact of stratospheric flight

In a manner analogous to our treatment of volvanically produced stratospheric aerosols, we calculated the ΔT from increases in stratospheric particles from SSTs and Space Shuttles operating at projected traffic levels for the next several decades[6,7]. The results of these calculations are given in Table 2. Again, an increase in aerosol population in the stratosphere leads to a cooling of the Earth.

The importance of the ($\Delta\tau$, ΔT) values shown in Table 2 can be partially assessed by comparing them with $\Delta\tau$s produced by volcanic eruptions and ΔT values associated with significant climatic changes. The largest $\Delta\tau$ that SSTs may produce is an order of magnitude smaller than the $\Delta\tau$s produced by very minor volcanic activity, such as the Andes eruption of 1920 shown in Fig. 1. Thus, the contribution to the number of stratospheric aerosols by aircraft and rockets over the next few decades will be less than the contribution by random, quite insignificant volcanic eruptions.

According to Table 1, past climatic changes with $|\Delta T|$ values of 4 K and 0.5 K characterise the difference between glacial and interglacial periods and between the Little Ice Age and the decade 1935–1945, respectively. Clearly, a cooling of the Earth by 4 K would be disastrous for Mankind, since past ice ages have been characterised by huge sheets of ice covering almost all of Canada, most of the northern USA, and parts of northern and central Europe and the USSR. While it involved a much less dramatic change, the climate of the Little Ice Age was also significantly different from that of the present century. For example, the precipitation pattern in a number of marginal agricultural areas was notably different from the current one and the length of the growing season at high latitudes was significantly shorter[33]. Thus, past climatic changes of as little as 0.5 K have had a serious practical impact. Changes of < 0.1 K would be less serious, however, than those that have occurred over the past several decades and would even be hard to measure. All the computed ΔT values of Table 2 are below this bound of 0.1 K; hence we conclude tentatively that the aerosols produced by vehicular traffic in the stratosphere over the next several decades will not have serious climatic consequences.

This conclusion can be put into some perspective by noting that about 70 Space Shuttle flights per day (against projections of < 1 per week) or 5,000 SSTs in operation (against projections of 250–1,500) would be required to decrease the surface temperature by 0 1 K. The conclusion thus reached on Space Shuttles is unlikely to be altered by future data, but the conclusion on the effect of high-flying aircraft should be re-evaluated as projections concerning their emission and flight characteristics are updated.

Finally, we note that the presence of additional particles in the stratosphere will have a negligible effect on the ozone cycle. For example, we estimate that the fractional increase in the ozone destruction rate due to scattering by the added particles is only ~ 0.1 of the $\Delta\tau$ values shown in Table 2 (ref. 7).

The toxicity of ^{90}Sr, ^{226}Ra and ^{239}Pu

M. C. Thorne & J. Vennart

MRC Radiobiology Unit, Harwell, Didcot, Oxfordshire OX11 0RD, UK

Data now available on the risks of radiation-induced fatal cancer and hereditary disease and radionuclide metabolism suggest that limits on the rates of intake of ^{90}Sr, ^{226}Ra and ^{239}Pu at work, presently recommended by the International Commission on Radiological Protection, might be in need of considerable revision one with another and with the limit for uniform exposure of the whole body.

DISCUSSIONS on this subject often centre on the values of maximum permissible body burden (MPBB) recommended by the International Commission on Radiological Protection (ICRP)[1]. For example, Spiers and Vaughan[2] considered the risk of osteosarcoma, cancer of the air sinuses and leukaemia arising from ^{226}Ra and ^{239}Pu in the skeleton, and they concluded that the currently recommended values of MPBB for these radionuclides do not need major revision. As Spiers and Vaughan[2] acknowledged, however, the recommendations of ICRP limit the rate of intake of radioactive materials into the body so that the MPBB for a well retained, long lived radionuclide will not be reached until the end of a working lifetime of 50 yr. In such circumstances, MPBB might be regarded more as an index by which to judge whether an individual has been overexposed, than as a quantity useful in planning for work with the radionuclide concerned. For this latter purpose, the corresponding maximum permissible annual intake (MPAI) is more pertinent. Values of MPAI may be obtained from the values of maximum permissible concentration in air or water (MPC) recommended by the Commission[1]. It is worth noting that, even if there were no debate about the relationship between risk of an effect and dose, there might now be a need to revise values of MPAI because of the data on the uptake and retention of radionuclides in body tissues which have become available since the recommendations were made.

The recommended values of MPAI for each radionuclide are different for soluble and insoluble compounds and for inhalation and ingestion. Using methods similar to those described in the MRC report on the toxicity of plutonium[3], we have estimated by way of example, the total risk of fatal cancer and serious hereditary disease arising from currently recommended values of MPAI for ingested soluble ^{90}Sr and ^{226}Ra and inhaled insoluble ^{239}Pu. We show that in these three cases the values of MPAI may be in need of considerable revision.

Relationships between risk and dose

Data on the risk of radiation-induced fatal cancer and hereditary disease have been reviewed by a United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR)[4] and a National Academy of Sciences Advisory Committee on the Biological Effects of Ionizing Radiations (BEIR)[5]. Both reports adopt the hypothesis that the risk of an effect is linearly related to dose. We have used the information in these reports to obtain the values discussed below and because they are based on a hypothesis which cannot yet be proved at the low doses concerned in radiological protection, they must be regarded as 'nominal' risks.

Leukaemia. Epidemiological studies on the survivors of the A-bomb explosions at Hiroshima and Nagasaki show an increasing leukaemia incidence with increasing dose. From the BEIR report[5], the estimated incidence is 20–50 cases per 10^6 people exposed to 1 rad ($20-50/10^6$/rad), in good agreement with the UNSCEAR estimate[4] of 15–40 cases/10^6/rad and the estimate of Smith and Doll[6] of about $20/10^6$/rad. We have chosen a value of $30/10^6$/rad for radiation of low linear energy transfer (LET).

Breast cancer. Data on breast cancer incidence in women survivors of the A-bombs and in tuberculosis patients subjected to multiple X-ray fluoroscopies show an incidence rate of between 3 cases/10^6/yr/rad (UNSCEAR) and 6 cases/10^6/yr/rad (BEIR). We have assumed a 20-yr period of increased incidence to yield a morbidity of about 90 cases/10^6/rad. Since the 5-yr survival of patients treated for breast cancer is about 50% (ref. 4) we have chosen a rounded value for the incidence of fatal breast cancer in females of $50/10^6$/rad of low LET radiation.

Lung cancer. The UNSCEAR report gives an estimate of 10–40 cases/10^6/rad of high dose rate γ radiation from A-bombs during the first 25 yr after exposure. This is in good agreement with the value in the BEIR report of 0.9 cases/10^6/yr/rem obtained from groups exposed to A-bomb radiations and to X rays in the treatment of ankylosing spondylitis. The value given in the BEIR report for exposure of the respiratory system to α rays from radon is 11.2 cases/10^6/yr/rad for a follow-up period of about 25 yr. Using a value of 20 for the quality factor for α rays (*vide infra*) this corresponds to a total risk of about 14 cases/10^6/rad of low LET radiation. Based on these two sets of data we have used a value of $20/10^6$/rad for low LET radiation.

Thyroid cancer. The UNSCEAR report estimates the incidence rate for thyroid cancer in adults to be in the range of 1 to 4 cases/10^6/yr/rad and the BEIR report does not give a numerical estimate. We have assumed a value of 2.5 cases/10^6/yr/rad and a 20-yr period of increased incidence, to give a total morbidity of 50 cases/10^6/rad. The 5-yr survival from thyroid cancer, however, is about 80% (ref. 4) and we have chosen a value $10/10^6$/rad of low LET radiations for the risk of radiation-induced fatal thyroid cancer.

Osteosarcoma. There is little information on the induction of osteosarcoma by external radiation. From data on patients treated with X rays for ankylosing spondylitis, the BEIR report gives an estimate of 0.034–0.22 cases/10^6/yr/rad average dose to bone over a follow-up period of 5–27 yr. The BEIR report also gives an estimate of 0.11 cases/10^6/yr/rem average dose to bone for persons contaminated with ^{226}Ra. This value is based on a

quality factor of 10 for α particles and a follow-up period of 49 yr. It is, therefore, approximately equivalent to a risk of 110 cases/10⁶/α rad to cells on the endosteal surface of bone which receive about half the average dose in bone. This is in good agreement with the estimate by Spiers and Vaughan[2] of 95 cases/10⁶/α rad to the endosteum. We have, therefore, taken a risk estimate of 100/10⁶/rad to the endosteum for high LET radiation and 5/10⁶/rad for low LET radiation, the latter being consistent with data from the BEIR report and the quality factor of 20 for α particles (*vide infra*).

Air-sinus carcinoma. In persons contaminated with ²²⁶Ra the risk of air-sinus carcinoma induction is about 40% of that of osteosarcoma[2], however, no such cancers have been induced in patients treated with ²²⁴Ra (ref. 5). These data suggest that the air-sinus carcinomas arising in persons contaminated with ²²⁶Ra are a result of irradiation of the air-sinus epithelium by ²²²Rn and its short lived radioactive daughters trapped in the air cavities of the sinuses[7]. Therefore, we have assumed the risk of air-sinus cancer to be zero in persons exposed to ⁹⁰Sr and ²³⁹Pu and to be 40% of the risk of osteosarcoma in persons exposed to ²²⁶Ra (compare Table 3).

Other cancers. In the A-bomb survivors, an excess of cancers other than those listed here has been observed. This excess is not sufficient, however, to break down into specific categories. The estimate for these 'other' cancers by UNSCEAR was about 40 cases/10⁶/rad during the 25 yr after exposure and by BEIR about 2.0/10⁶/yr/rem. We have used a value 40/10⁶/rad of low LET radiation for the combined total of all 'other' fatal cancers. In the case of inhaled insoluble ²³⁹Pu, the only 'other' tissue irradiated to any significant extent is the liver. For this organ we have used a risk estimate of 10/10⁶/rad of low LET radiation, derived from the MRC report[3] when allowance is made for the different values of the quality factor used here and by MRC.

Serious hereditary disease. The risk of genetic effects from irradiation of the gonads is particularly difficult to estimate. Both the BEIR and UNSCEAR reports considered that the risk from irradiating oocytes is considerably less than that from irradiating spermatagonia. UNSCEAR derives a best value of 20 cases of serious hereditary disease per 10⁶ in the immediate descendants of a male parent exposed to 1 rad of low LET radiation at low dose rate. Comparable estimates in the BEIR report for 1 rem to both parents, were 10–100 cases/10⁶ in the first generation and 50–500 at equilibrium. BEIR also estimated the increase in congenital anomalies, anomalies expressed later and constitutional and degenerative diseases after both parents had received 1 rem, to be 1–100 cases/10⁶ in the first generation and 10–1,000/10⁶ at equilibrium. For workers exposed to radiation, the relevant risk is probably that of serious hereditary disease in their immediate descendants and for this we have chosen a value of 50 cases/10⁶ for a worker receiving 1 rad of low LET radiation. The appropriate value for irradiation of the general population, if evaluated over many generations, would be greater, and greater still if diseases of less severity were taken into account.

Table 1 'Nominal' risk of fatal cancer and serious hereditary disease per unit dose

Effect	Tissue at risk	Cases/10⁶/rem Male workers	Cases/10⁶/rem Female workers
Leukaemia	Red bone marrow	30	30
Breast cancer	Female breast	—	50
Lung cancer	Lung	20	20
Thyroid cancer	Thyroid	10	10
Osteosarcoma	Cells on endosteal surfaces	5	5
Liver cancer	Liver	10	10
Other cancers	All other tissues	30	30
Hereditary disease	Gonads	50	50
Total	Whole body	155	205

The various risk estimates discussed above are summarised in Table 1 and are given per rem. In the calculations of dose equivalent discussed below it will be assumed that a quality factor (*Q*) of unity applies for low LET radiations and 20 for α particles as recommended[8]. The value of 20 for α particles is supported by cytogenetic work with ²³⁹Pu (ref. 9) and experiments on chromosome damage in liver cells with low dose rate radiation[10]. A value of 20 is also compatible with the data on osteosarcoma induction mentioned above. ICRP used a value of 10 in its 1959 recommendations[1], as did the MRC[3].

Dose commitment per unit activity taken into the body

Since it is assumed that risk of an effect is linearly related to dose, risk in any organ or tissue from intake of radionuclide is proportional to the resulting average total dose received by that tissue (the dose commitment) before induction of the effect. The tissues considered to be at risk are shown in Table 1. Their masses have been taken from the data given by ICRP for Reference Man[11]. Metabolic models for the three radionuclides under discussion have been proposed in the reports of two ICRP Task Groups[12,13].

For inhaled insoluble ²³⁹Pu we have used the lung model proposed in ref. 12 to calculate the dose commitment in lung (comprising the trachea, bronchi, pulmonary region and associated lymph nodes) and the fractions of ²³⁹Pu transferred to the gut and the blood. We have assumed the inhaled particles to have an activity median aerodynamic diameter (AMAD) of 1 μm, however, differences in particle size within the range likely to be encountered in practice will not markedly affect the results[3]. The dose to the walls of the gut is small compared with that in other tissues because of the limited range of the α particles and the position of sensitive cells[3]. Of ²³⁹Pu entering the blood, a fraction (0.45), is assumed to reach both bone and liver and be retained with half lives of 100 and 40 yr respectively[12]. From data of Richmond and Thomas[14] we have estimated that of ²³⁹Pu entering blood 10⁻³% is deposited per g of testes or ovaries and remains there indefinitely[15], and from experimental work in our unit, the dose to the spermatogonial stem cells is taken to be 2.5 times the average dose in the testes[15]. Our experimental work on female mice so far has not suggested that the dose to maturing oocytes is very different from the average in the ovary.

Average doses to cells on endosteal surfaces (taken to lie within 10 μm of the bone surface) and to haematopoietic bone marrow have been calculated for ²³⁹Pu and ²²⁶Ra using the Monte Carlo techniques described by Thorne[16]. ²³⁹Pu was assumed to be distributed uniformly in a thin layer over all endosteal surfaces and ²²⁶Ra in the volume of mineral bone (details of these calculations will be published elsewhere). Doses to the endosteum and red bone marrow from ⁹⁰Sr have been calculated using the data of Whitwell and Spiers[17].

For ingested soluble ⁹⁰Sr and ²²⁶Ra, the fractional absorption from the gut has been taken as 0.3 and 0.2 respectively[13]. The value for ⁹⁰Sr is a compromise between the value 0.2 given in ref. 13 and the mean value 0.38 given in ref. 11. Values for the time integral of activity of ⁹⁰Sr and ²²⁶Ra in trabecular and compact bone and in the soft tissue of the body have been derived using data in ref. 13. ⁹⁰Sr is assumed to be in equilibrium with its short lived daughter ⁹⁰Y in all organs and tissues of the body at all times after ingestion. All ²²²Rn produced from ²²⁶Ra in the soft tissues of the body is assumed to escape from the body before it decays. Of ²²²Rn produced in bone, 30% is assumed to remain at its production site, where it gives up the α energy of all its daughters except that of ²¹⁰Po, which follows the long lived ²¹⁰Pb. The remaining 70% is assumed to escape from the body without imparting any energy to tissues[1]. For both ingested soluble ⁹⁰Sr and ²²⁶Ra, the dose to the gut is very much smaller than that to the other organs and tissues shown in Table 2 and it has been neglected.

Values are given in Table 2 for the dose commitments in various organs and tissues of the body from ingestion of 1 μCi

Table 2 Dose commitments in various organs and tissues of the body from ingestion of 1 µCi of soluble [226]Ra, ^{90}Sr and inhalation of 1 µCi of insoluble [239]Pu

	Dose commitment (rem µCi⁻¹)		
Tissue at risk	Ingested [226]Ra	Ingested [90]Sr	Inhaled [239]Pu
Red bone marrow	2	0.7	300
Female breast	0 4*	0.005*	—
Lung	0.4	0.005	1200
Thyroid	0.4	0.005	—
Cells on endosteal surfaces	20	0.9	3700
Liver	0.4*	0.005*	760
All other tissues	0.4	0.005	—
Gonads: Male	0.4	0.005	38
Female	0.4	0.005	15

* [90]Sr and [226]Ra are assumed to be uniformly distributed in soft tissues[11,12].

of soluble [226]Ra and ^{90}Sr and from inhalation of 1 µCi of insoluble [239]Pu. For the gonads, dose has been integrated over an assumed reproductive life of 20 yr and for other tissues, over a working life of 50 yr. These dose commitments therefore only apply to intakes which occur early in the working life.

Risk per unit activity taken into the body

Values of the 'nominal' risk per unit intake of the radionuclides were derived from the data in Tables 1 and 2 and are shown in Table 3. The risk estimates apply to intakes early in life and are overestimates of the true risk, in the sense that some cancers induced late in life will not be recognised because of their latent periods. Several aspects of the risks shown in Table 3 are worth noting.

(1) For [226]Ra a risk of leukaemia, about half that of osteosarcoma, seems at variance with human experience: in people containing the radionuclide, the incidence of leukaemia has been about ten times' lower than that of osteosarcoma[2]. A plausible explanation for this disparity might be that the use of an arbitarily defined quality factor of 20 for α particles[8] overestimates the risk of leukaemia relative to that of osteosarcoma. An alternative explanation concerns the distribution of cells sensitive to leukaemia induction within red bone marrow and the relationship between risk of an effect and dose for those cells. Cells in marrow at distances greater than the range of α particles (about 40 µm) from bone receive no dose from α particles arising in bone and cells nearer to bone receive increasing doses the nearer they are. Our estimates of the risk of leukaemia have been obtained from the estimated average dose in marrow and the observed risk of leukaemia per unit dose to the marrow of people who were uniformly irradiated either with A-bomb radiations or X rays. Therefore, our estimates will be in error if the sensitive cells are not uniformly

distributed in the marrow or if the dose–response relationship is not linear over the range of doses concerned. With regard to the latter, the lifetime doses to marrow which are of interest in radiological protection are within the range from which risk estimates were obtained[4,5]. It is possible, however, that the assumption of linearity overstates the risk at low dose rates. Conversely, if a significant proportion of sensitive cells lie near to bone, we might have underestimated the risk of leukaemia because such cells receive doses much greater than the average in the marrow. We have experimental evidence that the incidence of myeloid leukaemia in mice reaches a maximum value at average doses in marrow of about 200–300 rad of X rays (I. Major and R. H. Mole, personal communication) presumably because at greater doses, the sterilisation of transformed cells exceeds their production. Smith and Doll[5] have also drawn attention to this breakdown of the linear dose–response hypothesis to explain the absence of leukaemia in women treated for cancer of the cervix who received very large doses to small volumes of marrow[18]. In the radium cases exhibiting osteosarcoma[2], marrow cells near to bone received very large doses. If a significant proportion of marrow cells sensitive to leukaemia induction are near to bone, this might explain the low incidence of leukaemia observed. By contrast, it is interesting that osteosarcoma incidence in these radium cases was increasing at α-particle doses to cells within 10 µm of endosteal surfaces of 500 rad (10,000 rem) or more[19]. Clearly, more information is required about the distribution of the cells which are sensitive to induction of both osteosarcoma and leukaemia.

(2) For [226]Ra the predicted risk of hereditary disease is about 8% of the total risk, corresponding values for ^{90}Sr and [239]Pu are 1 and 2% respectively. These percentages would increase for populations exposed to the radionuclides for long periods.

(3) The risk of leukaemia predominates for [90]Sr. The relative risk of leukaemia to osteosarcoma for both ^{90}Sr and [239]Pu is much greater than would be expected from experiments on animals. Most of these experiments have, however, been conducted in ways which might not have favoured the incidence of myeloid leukaemia as discussed in (1) above.

(4) Although all three radionuclides are commonly referred to as "bone-seekers", these predictions show that risk arises mainly from irradiation of the skeleton and its marrow only in the case of ingested [90]Sr (98% of the total); for ingested [226]Ra, the risk from irradiating the skeleton is about 65% and for inhaled [239]Pu, about 45% of the total. In the last case, about 40% of the risk arises from irradiation of the lung.

We acknowledge that the estimates of 'nominal' risk we have made are open to criticism and that the data on which they are based have been interpreted in different ways (see, for example, ref. 20). There is also considerable uncertainty concerning estimates of dose and the relevant tissues at risk. Nevertheless, the estimates of 'nominal' risk (Table 3) were derived from the most recent data in official reports and it is interesting to

Table 3 'Nominal' risk per unit activity of soluble [226]Ra and ^{90}Sr ingested and insoluble [239]Pu inhaled, for male and female workers

	Cases/10⁶/µCi					
Effect	Ingested [226]Ra		Ingested [90]Sr		Inhaled [239]Pu	
	MW	FW	MW	FW	MW	FW
Leukaemia	60	60	21.00	21.00	9,000	9,000
Breast cancer	—	20	—	0.25	—	—
Lung cancer	8	8	0.10	0.10	24,000	24,000
Thyroid cancer	4	4	0.05	0.05	—	—
Osteosarcoma	140*	140*	4.5	4.5	18,500	18,500
Liver	4	4	0.05	0.05	7,600	7,600
Other cancers	12	12	0.15	0.15	—	—
Hereditary disease	20	20	0.25	0.25	1,900	750
Total	248	268	26.1	26.35	61,000	59,850

* Increased from 100 to 140 to allow for the risk of air-sinus carcinoma in persons exposed to [226]Ra.

Table 4 Annual limits on exposure recommended by ICRP; the resulting values of MABB after exposure for 50 yr and the risk from 1 yr of practice exposed to the limits

Exposure	Annual limit	MABB (μCi)	'Nominal' risk (cases per 10,000 per year)
Ingested soluble ^{226}Ra	0.08 μCi	0.005	0.2
Ingested soluble ^{90}Sr	0.8 μCi	0.37	0.2
Inhaled insoluble ^{239}Pu	0.07 μCi	0.16	40
Irradiation of whole body	5 rem		9

consider the consequences of applying these estimates to current recommendations of the ICRP.

Body burdens and risk from the MPAIs recommended by the ICRP

The values of MPAI recommended at present by the ICRP for the radionuclides under discussion are shown in Table 4. They were obtained directly from the values of MPC recommended by ICRP, assuming that a Reference Man[11] takes in 2,200 cm^3 of water and inhales 2×10^7 cm^3 of air each day. Table 4 shows the maximum achievable body burden (MABB) which such a man could attain at the end of 50 yr if he were exposed to the MPAI each year for that period. The values for ^{90}Sr and ^{226}Ra of 0.37 and 0.005 μCi respectively have been obtained using the data given in ref. 13. About 90 and 80% of the ^{90}Sr and ^{226}Ra respectively, would be in bone and the remainder in soft tissues. These values of MABB are about 5 and 20 times less than those of MPBB recommended at present[1], namely 2 and 0.1 μCi for ^{90}Sr and ^{226}Ra respectively, of which 99% was assumed to be in bone. Values of MPC, and therefore of MPAI, were calculated to result in values of MPBB after a 50-yr exposure and the ratio of the presently estimated values of MABB to the recommended values of MPBB demonstrates the effect of using the new metabolic data now available[13]. No value of MPBB was given by ICRP[1] for inhaled insoluble ^{239}Pu, its intake being limited by the dose in lung. The value of MABB shown in Table 4 (0.16 μCi) was derived using the data from ref. 12. About 40% of this MABB will be in bone, about 30% each in liver and lung and only a small percentage in other soft tissues, including the gonads. The value of MPBB commonly used for ^{239}Pu (0.04 μCi) was derived by assuming that 90% of the activity would be in bone and is four times smaller than the value of MABB calculated here.

The average 'nominal' risks for men and women arising from the MPAIs are also shown in Table 4 and, for comparison, that arising from the dose limit of 5 rem to the whole body[20] recommended at present, assuming a 'nominal' risk of 180 cases per 10^6 per rem, which is a representative value for men and women (Table 1). Since it is reasonable to expect that the risk from exposure to each of the various limits should be the same, the three values of MPAI and the dose limit for whole-body exposure are clearly in need of revision one with another. If it were agreed that the risk from exposure of the whole body

to 5 rem each year is acceptable to workers, then the MPAI for inhaled insoluble ^{239}Pu would have to be revised down by a factor of about five and those of ^{90}Sr and ^{226}Ra both revised up by a factor of about 50. The ICRP is at present revising its recommendations and will no doubt ensure that the hazards from occupational exposure will not exceed those that are accepted in most other industrial or scientific occupations with a high standard of safety (para. 47 of ref. 21). In this respect, the MRC report[3], quoting a paper by Pochin[22], compared the risk from an MPAI with the average risk of fatalities in other kinds of work for which there seems to be a dividing line at 1 in 10,000 per year between the relatively safe and less safe industries. Comparisons of this kind need to take account of many social and economic factors, discussion of which is outside the scope of this paper. Whatever may be the outcome of discussions on these matters, however, it seems likely that many values of MPAI will need to be revised, not always in the same direction, because of new data on the fate of radioactive materials after they have entered the body.

Darwin's finches and the evolution of sexual dimorphism in body size

Jerry F. Downhower

Department of Zoology, The Ohio State University, Columbus, Ohio 43210

A simple model based on certain bioenergetic phenomena accounts for seasonal patterns of sexual dimorphism, size related changes in the timing of reproduction and geographic variation in body size of Darwin's finches.

SEXUAL dimorphism in size influences the biology of birds in many ways; for example, differences in beak size determine the size and kind of food that a bird can capture and ingest[1-3]. Consequently, monogamous pairs that differ in size may increase the rate at which they feed their nestlings, since the adults do not compete for the same food items[1,2]. Interspecific aggression[4]

or intraspecific aggressive conflicts between males, where increased size could influence the outcome, may account for the general avian condition that males are the larger sex[2]. In addition, sexual differences in size may facilitate pair formation[5,6].

Many observations indicate that sexual dimorphism in body size may be subject to another equally broad explanation. First, among monomorphic species, sexual differences in behaviour result in each sex foraging on different things in different places[7-10]. Second, full adult size is generally achieved at fledging, and certainly before first reproduction, so increased male size in polygynous species may reduce the risks associated with delayed sexual maturation in males[11]. Third, sexually dimorphic species in which the female is the larger sex require special explanations[12-14]. Finally, since beak and body size are correlated, dietary differences associated with beak size may be an inevitable consequence of the advantages associated with size alone.

Here I examine the proposition that sexual dimorphism in body size influences the timing of reproduction in fluctuating and seasonal environments. Evidence favouring the hypothesis is drawn from general studies on the energetic consequences of differences in body size, Lack's studies on morphological variation in Darwin's finches, and from my own studies of the reproductive biology of *Geospiza conirostris* and *G. fuliginosa*, two seed-eating finches that inhabit Española, the southernmost of the Galápagos Islands.

The influence of body size

Body size (weight) influences the rate at which birds use energy. Resting metabolism, the energetic costs of flight[16], and existence metabolism[17] bear an exponential relationship to body weight as do egg weight[18], heart rate and conductance[19]. In general, the exponent of these relationships is less than 1.0. In contrast, functions describing the storage capacity or energy reserves of a bird, for example, digestive capacity, and lipid reserves[20],-bear a nearly linear relationship to body weight. These different relationships affect the ability of a bird to respond to periods of deprivation and surfeit.

Consider two birds differing only in weight that are subjected to a physiological stress such as fasting or water deprivation after having been maintained on an *ad libitum* diet. To withstand this period of stress, they draw on stored reserves. The rate at which the larger (R_L) or the smaller (R_s) individual uses energy is dependent on body weight and can be expressed as follows

$$R_L = aW_L{}^b$$
and
$$R_s = aW_s{}^b$$

where W_L and W_s are the weights of the larger and smaller individuals. Since a and b are constants, R_L is always greater than R_s.

How long (T_L, T_s) each individual persists, depends on the size of its reserve ($cW_L{}^d$ and $cW_s{}^d$) and the rate at which energy is used

$$T_L = cW_L{}^d/R_L = \frac{c}{a} W_L{}^{(d-b)}$$

and

$$T_s = cW_s{}^d/R_s = \frac{c}{a} W_s{}^{(d-b)}$$

where c and d are constants. As long as d is greater than b, T_L will be greater than T_s and the larger individual will persist longer than the smaller. It also follows, that when confronted with a surfeit of resources, the smaller individual can replenish its reserves faster than the larger ($R_L > R_s$), provided that size does not influence the efficiency of uptake in any disproportionate way.

This analysis of the consequences of differences in body size is inherent in explanations of geographical variation in size of Atlantic salmon (*Salmo salar*)[20], cricket frogs (*Acris crepitans*)[21],
Fig 1 Rankings of culmen length and island size for populations of (a) *Geospiza fuliginosa* and (b) *Certhidea olivacea*. Culmen length data are taken from Lack[15]; island sizes are given by Bowman[28]. a, $R_s = -0.55$, $P < 0.05$, $n = 15$; b, $R_s = -0.44$, $P < 0.05$, $n = 16$.

wood rats (*Neotoma* sp.)[22], and has been expanded in detail for birds by Calder[19].

In fluctuating environments, consequences of differences in body size may become important. Among temperate species, periods of inclement weather alter foraging behaviour[23], and severe weather conditions can alter the survivorship of conspecifics that differ in body size[24,25].

Darwin's finches and the Galápagos

The lowlands of the Galápagos Islands are dry, hostile places, but on the larger islands these 'arid zone' forests give way to more mesic environments at higher elevations[26] and on these islands, Darwin's finches migrate from the arid coast to the highlands during periods of drought[26,27]. On smaller, low lying islands, migration may be useless since the entire island may be covered with arid zone vegetation, so the finches are more likely to be subjected to periodic stress than would conspecific populations on larger islands. It follows from the analyses of the consequences of body size that finches on small islands should be larger than conspecifics on large islands.

Geospiza fuliginosa, the smallest of the seed-eating Geospizinae, occurs on many islands in the Galápagos, as does *Certhidea olivacea* the smallest insectivorous finch in the archipelago[17,18]. In both cases, the birds on small arid islands tend to be larger than their conspecifics on larger islands (Fig. 1). Although this trend is consistent with the conclusion that increased size provides some resistance to environmental change, it is also consistent with the idea that size is determined by diet[2], since both seeds[29] and insects[30] are likely to be larger in more arid environments. The size and frequency distributions of seeds and insects on islands in the Galápagos are not known, but the effects of differences in prey size and climatic variability are complementary, in that both would select for larger size on smaller islands.

Body size and timing of reproduction

The reproductive patterns and life histories of vertebrates are also influenced by differences in body size. Large species generally mature slowly, produce small clutches, and are long lived, whereas smaller species mature more rapidly, produce larger clutches and are shorter lived[31]. The possibility that differences in body size would influence the timing of reproduction in seasonal environments has not been investigated.

Consider two species, with similar ecologies and competitive abilities, that differ in body size. On the assumptions that reproduction is initiated by a variable environmental cue and that the energy for egg production is derived from currently available food supplies rather than from stored reserves, it follows that females of the smaller species are likely to accumulate the necessary energy for egg production sooner than those of the larger species because they have a reduced maintenance cost[19]. The smaller species should, therefore, breed earlier than the larger species (Fig. 2a).

Fig 2 A graphic model for size-dependent changes in the timing of reproduction. Sm, Smaller species; Lg, larger species. See text for discussion.

its breeding population is at a maximum level (Fig. 2b) and shifts into a nestling phase (nestlings present in more than half the nests) before the population of the smaller species does so (C in Fig. 2c). Since the smaller species can establish nests until somewhat later, it will not achieve maximum densities until then (Fig. 2b), and so it enters the nestling phase (D in Fig. 2c) later than the larger species.

My studies of the reproductive biology of two species of Darwin's finches, *Geospiza fuliginosa* and *G. conirostris*, provide a direct test of the foregoing model.

Darwin's finches on Española

I visited Española in July 1972 and again in January and February 1973. On both occasions I netted, weighed, measured and banded birds in the vicinity of Punta Suárez and searched that area for active nests (unpublished). Some birds were breeding during my first visit, but most breed during the rainy season (January–March)[32]. During my second visit, I collected crop samples from nestlings of both species. On Española, individual *Geospiza fuliginosa* weigh 14–16 g; whereas individual *G. conirostris* weighed from 25 to 39 g. Although these birds differed in body size, their breeding biologies were remarkably similar: both commonly incubated clutches of three eggs (range 1–5) and required about 30 d to complete a clutch and fledge their young; and both showed similar preferences for nest sites (my unpublished results) and the diets of their nestlings were also similar.

The diets of nestling *G. conirostris* contained 17% seeds with the remainder being composed of a variety of invertebrates. *G. fuliginosa* nestlings received a diet composed of 35% seeds. Both species fed the same kinds of seeds to their nestlings (Table 1). Of the over 5,000 seeds recovered from nestling *G. conirostris*, 95% by count and 88% by volume were of one species of grass, *Panicum hirticule*. This species also accounted for more than 86% of the >8,000 seeds recovered from *G. fuliginosa* young, and made up more than 80% of the volume of seeds in those samples. Thus, for both finches, the same grass species accounted for 80–90% of seed material that they fed to their nestlings.

Lepidoptera larvae of various sizes made up over 96% of the

If clutch size is similar for both species, then the larger species will require more food to support its young, since they are larger; and if the breeding season is terminated by a decline in available food, the breeding season of the larger species will end before that of the smaller. A major effect of size will thus be to shorten the breeding season for the larger species (Fig. 2a).

The differences in length of the breeding season for species of different sizes will alter the observed patterns of reproduction at the population level (Fig. 2b and c). Presume first that a few individuals are breeding throughout the year. When a breeding season starts, the establishment of new nests and production of new clutches will shift the relative proportions of nests with eggs away from 50% (Fig. 2c). The deviation of the population towards a surplus of nests with eggs will be countered as soon as the first eggs hatch. The same pattern will occur for the larger species, except that it will occur later. There is thus a period when the smaller species is in the incubation phase (more than half the nests have eggs) of a nesting cycle and the larger species is not (A in Fig. 2c). Since the larger species nested later, its population will seem to remain in incubation phase longer than the smaller species (B in Fig. 2c). As the end of the breeding season approaches, the larger species ceases establishing nests,

Fig. 3 Frequency distribution for the sizes of lepidoptera larvae recovered from nestling *Geospiza fuliginosa* and *G. conirostris* in February 1973. Total no. of larvae: *G. fuliginosa*, 838; *G. coniros-tris*, 172.
Table 1 The relative numbers of different kinds of seeds recovered from nestling *G. conirostris* and *G. fuliginosa*

Source	Seed volume (mm³)	Percentage occurrence *G. conirostris*	*G. fuliginosa*
Seeds smaller than			
P. hirticule	0.50 ± 0.029	0.6	
	0.13 ± 0.002		1.6
Panicum hirticule	0.69	93.6	86.5
Seeds larger than			
P. hirticule	1.10 ± 0.012	5.6	
	1.06 ± 0.005		11.7
Total number of seeds recovered		5,170	8,262

volume of invertebrates recovered from nestling *G. conirostris*, and 76% in the diets of *G. fuliginosa* young (Fig. 3). Small larvae were present in the diets of both species, but large larvae were more common in the diets of *G. conirostris* ($t = 4.04$, $P<0.001$). Over 30% of the larvae recovered from *G. conirostris* nestlings were 20 mm long or longer, whereas larvae of this size accounted for less than 3% of the larvae in the diet of *G. fuliginosa* nestlings. In total, larvae of lepidoptera and the seeds of *P. hirticule* alone accounted for 96% and 80% (by volume) of the food items that *G. conirostris* and *G. fuliginosa* fed to their young.

Nestling diets changed during the course of my study (Table 2). Small larvae (<20 mm in length) always composed 80% or more of the larvae recovered from nestling *G. fuliginosa* during the period February 15 to March 2; whereas, large larvae (>20 mm) became an increasingly rare dietary item for nestling *G. conirostris* and small larvae became more common. This change influenced the overall dietary balance for nestling *G. conirostris*. In mid-February, diets of nestling *G. conirostris* contained 94% animal matter (by volume) whereas by March 2,

animal matter accounted for less than 50% of their diet. Thus, the diets of nestling *G. conirostris* showed a progressive deterioration late in the study, a change that was independent of nestling weight, and not observed in the diets of nestling *G. fuliginosa* (Table 2). These findings are not inconsistent with the assumptions and expectations of the model. The species are similar in a variety of ways, and changes in the nestling diets occur first in the larger species. The temporal patterns of reproduction for both species are also instructive.

It is likely that some breeding occurs throughout the year for both of these species (D. Werner and P. Kramer, personal communication). When I visited Española in January and began to follow the course of activities at various nests, neither species had as yet entered the incubation phase of the breeding cycle (Fig. 4). The *G. fuliginosa* population entered the incubation phase in interval 4 and that population was dominated by nests with eggs until interval 10. The incubation phase began later for *G. conirostris* (interval 8) and a significant majority of nests had eggs until interval 12. Thus, the incubation phase began earlier

Fig. 4 Temporal changes in the percentage of nests with eggs for *Geospiza fuliginosa* (★) and *G. conirostris* (●). An arrow indicates a significant departure from a 1:1 ratio. A double-headed arrow indicates that there are differences between the two species as well. The data are summarised at 2-d intervals beginning on January 22 and ending on March 2, 1973.
and terminated earlier for *G. fuliginosa*, the smaller species, than it did for *G. conirostris* (compare with Fig. 2c). Exactly the reverse pattern occurred for the onset of the nestling phase. The nestling phase for *G. conirostris* began in interval 16, whereas for *G. fuliginosa* it was delayed until interval 18 (again compare with Fig. 2c). Finally, as expected from the model (Fig. 2b), *G. conirostris* had completed a maximum number of nests (interval 8) before *G. fuliginosa* (interval 14). In short, the observed nesting pattern in both species is identical to that expected from the model and suggests that the larger species, *G. conirostris*, does, indeed have a shorter breeding season than its smaller counterpart.

Seasonal sexual dimorphism in *Geospiza conirostris*

The analysis initially considered comparisons between species because size-related differences in their biology are more easily detected, but the model applies with equal force to individuals of the same species but different size.

During a major breeding season, all females are likely to breed, and so it would be difficult to determine if smaller females of the same species were breeding earlier, later, or were more likely to renest. If a short breeding season occurs, however, then females of small size may breed when the large ones do not.

The Galápagos are affected by the *el niño* phenomenon[33]. This event, which is tied to movements of ocean currents, has the effect of producing wet season (December–March) rains during the dry season (June–August) and thereby creating conditions similar to those in the breeding season. My first visit to Española occurred during an *el niño* year, therefore a comparison of the size of the birds breeding in July with those breeding in January provides a further test of the model.

In July 1972, I netted 225 *G. conirostris*; of which 17 were females with brood patches, and 14 were males in all-black plumage. During the same visit, I located five active *G. conirostris* nests and 15 active *G. fuliginosa* nests. During my winter visit, I netted 231 *G. conirostris*; of which 75 were females with brood patches, and 43 were mature males. In addition, I located 99 *G. conirostris* nests, and the male at 80 of these successfully attracted a female. The occurrence of few active nests in July suggests that *G. conirostris* had recently ceased breeding, and the paucity of adults in reproductive condition indicates that only a few individuals attempted to breed in July.

During the January–March breeding season there was no difference in size between males and females (Table 3). Although the mean size of females was less than that of males, the difference is insignificant. In contrast, however, the females breeding in July were significantly smaller than males both in body weight ($F_{1,30} = 12.5$, $P < 0.001$) and in culmen (beak ridge) length ($F_{1,30} = 5.15$, $P < 0.05$). Further, the females in breeding condition in July were significantly smaller than females that bred in January, both in body weight ($F_{1,91} = 6.78$, $P < 0.01$) and in bill size ($F_{1,91} = 6.60$, $P < 0.05$). Again the observed pattern was as expected from the model.

The extent to which smaller females will have additional opportunities to breed will depend on the frequency with which differential cues occur. The *el niño* vagaries of the Galápagos climate ensure that these events occur with some regularity. A consequence of this phenomenon is to depress the mean size of

females in the population, thus producing a sexually dimorphic population with regard to size.

The seasonal pattern of sexual dimorphism documented for *G. conirostris* and its suggested causes are not limited to large species, rather they should affect all species of finches in the archipelago. This seems to be the case. Lack[17,18] documented, but did not explain, the existence of sexual dimorphism in size in all except one of the Geospizinae—the Cocos Island finch (*Pinaroloxias inornata*), a species restricted to a humid tropical island just off the west coast of Costa Rica.

Size dimorphism in birds

Sexual dimorphism in size may result in differential resource partitioning[1,2,34]. Such partitioning occurs in Darwin's finches[35], but if it were a pervasive selective pressure for sexual dimorphism, it should manifest itself in assortative matings during the breeding season. That is, the male in each pair should consistently be larger, or heavier, than his mate. I have measurements on 12 pairs that bred in January. The male had a larger bill in five instances and was heavier in seven instances. Thus, although the sample is small, it gives no indication that assortative mating was occurring.

Sexual dimorphism has also been attributed to selection for increased size in males, which may be advantageous in male–male competition for breeding sites. In contrast, the finch data indicate that decreased female size resulted in increased fecundity in a fluctuating environment. In particular, small size in females increased their sensitivity to environmental changes that indicate favourable conditions for breeding. Smaller females are thus likely to breed sooner and more often than their larger counterparts.

My inferences concerning sexual dimorphism and its effect on the timing of reproduction in Darwin's finches are based on the consequences of certain bio-energetic relationships and depend on when the resources used for egg production are accumulated. If they are accumulated immediately before reproduction, then relatively small females will be at an advantage because they can accumulate the necessary resources more quickly. For small passerine birds, this is likely to be the case, and in house sparrows (*Passer domesticus*) in particular, Johnston and Sealander[34] have documented a trend of increasing sexual dimorphism with latitude, a finding which is consistent with the model since the timing of reproduction should be more critical in places with short growing seasons. Conversely, if resources for reproduction are derived from reserves stored at some other time, say, before migration, then larger females will be at an advantage because they will have more reserves left for egg production. It is notable that the degree of 'reversed sexual dimorphism' in the three species of Accipiters studied by Storer[13] increases with the degree of migration. Furthermore, certain species of shore birds, in which females are larger than males, arrive on their sub-arctic breeding grounds with substantial fat reserves[37], and the largest females breed first[6]. The timing of reproduction seems to be critical for these species; the arctic growing season is short and early breeding is associated with increased reproductive success[38]. In addition, Brodie[39] has detailed an identical explanation for reversed sexual dimorphism in fin whales (*Balaenoptera physalus*), in which the females store fat while feeding on krill in the Antarctic. They subsequently migrate northwards to their breeding grounds, which are characterised by warmer temperatures and reduced food productivity, where females give birth to and nurse their calves. The energy used during gestation and lactation seems to be derived from fat reserves stored in the Antarctic, and the larger size of females endows them with increased storage capacity to satisfy the demands of reproduction.

Larger male size is characteristic of many species of birds In certain North American species, males do not migrate as far South as females and overwinter in harsher climates, where increased size may reduce overwinter mortality. That migratory pattern seems to ensure the early arrival of males on the breeding ground[40]. In polygynous song birds, males generally arrive well

Table 3 Seasonal sexual dimorphism in *Geospiza conirostris*

Character	Date	Males n	Males Mean	Females n	Females Mean
Body weight (g)	July 1972	14	32.9 (0.66)	17	29.6 (0.62)
	January 1973	43	32.3 (0 37)	75	31.7 (0.34)
Culmen length (mm)	July 1972	14	14.0 (0.21)	17	13.3 (0.24)
	January 1973	43	14.1 (0.12)	75	13.9 (0.10)

Standard errors are given in parentheses.

in advance of the females and establish territories[41-43]. As a consequence, males are subjected to the rigours of territorial establishment at a time when the weather is likely to be inclement. Agonistic encounters are likely to reduce the time available for foraging and thus larger size may provide males with the physiological reserves necessary to hold a territory. This certainly seems to be the case in polygynous mammals. Male northern fur seals (*Callorhinus ursinus*) are 7–10 times the size of females[44], and establish territories before the arrival of the females. Territorial bulls fast for the duration of breeding season (2–4 months)[45]; Bartholomew[46] interprets the extreme sexual dimorphism in this species to be a result of the advantages of early territorial establishment and prolonged territory maintenance, advantages that could be realised by the increased storage capacities associated with increased size.

In summary, simple bioenergetic considerations provide a general description of geographic patterns of size variation, size-related changes in the timing of reproduction and seasonal patterns of sexual dimorphism in Darwin's finches. Expansion of these analyses provides a consistent explanation for patterns of normal and reversed sexual dimorphism in birds and mammals. The analysis accounts for the general condition of larger male size in temperate species and identifies the conditions that would lead to increased female size. In all certainty, these initial tendencies will be amplified by other selective pressures[2].

Chemical characterisation of the Thy-1 glycoproteins from the membranes of rat thymocytes and brain

A. Neil Barclay, Michelle Letarte-Muirhead* & Alan F. Williams

MRC Immunochemistry Unit, Department of Biochemistry, Oxford OX1 3QU, UK

Ralph A. Faulkes

National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

The Thy-1 antigens from both thymocytes and brain of rats are major membrane glycoproteins of about 25,000 molecular weight of which 30% is carbohydrate. The brain and thymus glycoproteins contain very similar amounts of each amino acid, but have strikingly different carbohydrate compositions. The antigenic determinants are likely to be in the protein part of the molecule.

MANY specific functions of cells are likely to be mediated by tissue specific molecules at the cell surface reacting with other cells or soluble factors. One method of identifying these is to study tissue-specific cell surface antigens, which are commonly referred to as differentiation antigens[1,2]. The theta (θ) antigen, now called Thy-1 (ref. 3) was one of the first cell-surface differentiation antigens to be identified on lymphocytes, and was found in mice in two allelic forms which were serologically identified as the Thy-1.1 (θ-AKR) and Thy-1.2 (θ-C₃H) alloantigenic determinants[4]. The Thy-1 locus is on chromosome 9 in the mouse[5].

The Thy-1 antigen was found in large amounts on mouse thymocytes and brain[4,6] and in smaller amounts on mature T lymphocytes[4,7,8]. The number of antigenic sites per thymocyte was found to be >400,000 for Thy-1.2 (ref. 8) and about 600,000 for Thy-1.1 (ref. 9) by measuring binding of the alloantibodies. The antigenic activity of brain is approximately equal to thymocytes on a packed tissue basis[4]. The Thy-1 antigen has also been reported on mouse epidermal cells and fibroblasts[10,11], but other tissues have very little if any antigen[4]. In the brain the Thy-1 antigen is present in small amounts at birth and increases to maximum specific activity after about 25 d (ref. 6).

The Thy-1.1 antigenic determinant can be recognised on rat thymocytes and brain with mouse alloantiserum, but no rat strain with the Thy-1.2 determinant has been reported[12]. The amount of antigen on rat and mouse thymocytes and brain in similar as is the developmental pattern in the brain but, surprisingly, most peripheral rat T cells lack the antigen, while many rat bone marrow cells express it at the cell surface[2,9,13]. Other tissues of the rat including erythrocytes, heart, kidney, lung and liver have virtually no detectable Thy-1 antigen[2]. Two other antigenic determinants

can be found on the rat Thy-1 molecule and these are recognised by xenogeneic (rabbit) antiserum and are referred to as the rat specific, and the rat–mouse cross reacting, xenoantigenic determinants[2,14]. Similar antigenic determinants have been described in the mouse[15].

There has been considerable confusion as to the chemical nature of the Thy-1 molecule with suggestions that it is a glycolipid[16,17], a protein of various sizes[18,19] or a glycoprotein[20,21] in mouse, and a protein or glycoprotein in rat[22]. Glycoproteins have been purified from rat thymocytes[23] and brain[24] which clearly carry all the Thy-1 antigenic determinants at high specific activities, and the conflicts between these results and the work of others is discussed below. The purifications involved the solubilisation of antigen in deoxycholate from crude membrane preparations, followed by gel filtration and affinity chromatography with columns of lentil lectin coupled to Sepharose-4B. The affinity column bound most of the brain Thy-1, but about 50% of thymocyte Thy-1 did not bind. This fraction was purified by an antibody column against brain Thy-1. Thus three Thy-1 preparations were obtained: brain Thy-1, thymocyte Thy-1 which binds to lentil lectin (Thy-1L+) and thymocyte Thy-1 which does not bind (Thy-1L−). The three preparations could not be distinguished by their antigenic determinants and both thymocyte and brain Thy-1 were of similar immunogenicity in rabbits. In contrast, slight differences in mobility of the glycoproteins were noted after electrophoresis on polyacrylamide gels in sodium dodecyl sulphate. On 12.5% polyacrylamide gels, brain Thy-1 had an apparent molecular weight of 24,000, while for thymocyte Thy-1L+ and Thy-1L− the values were 25,000 and 27,000, respectively[23,24].

We describe here the results of amino acid and carbohydrate analysis of the Thy-1 glycoproteins and also report experiments to determine the nature of the antigenic determinants.

Preparation of Thy-1 samples for chemical analysis

The three forms of Thy-1 were purified from rat thymocytes and brain as before[23,24] (except that twice recrystallised sodium deoxycholate was used) and the minor impurities in thymocyte Thy-1L− were removed by gel filtration on a column of Sephadex G-200 in 0.5% sodium deoxycholate. The purified fractions contained a large amount of deoxycholate after concentration by ultrafiltration, and this was removed by precipitation of the glycoprotein with ethanol in which deoxycholate is soluble (M. J. Crumpton, personal communication). Ethanol was added to a final concentration of 75%, together with a few drops of saturated sodium acetate in ethanol (to improve flocculation of the precipitate) and the mixture was left for 48 h at −20 °C. The precipitate was recovered and washed in absolute ethanol by centrifugation at 1,800 g for 30 min at −10 °C. The precipitates were readily soluble in water, and a small amount of turbidity was removed by centrifugation at 100,000g for 30 min. The resulting pellets contained less than 5% of the Thy-1 by antigenic activity or amino acid and carbohydrate analysis, and probably consisted of trace impurities from the deoxycholate.

This precipitation gave yields of 70% for both thymocyte forms and 40% for Thy-1 from brain. The procedure had no effect on the antigenicity of the glycoproteins whose specific activities for Thy-1.1 and Thy-1 xenoantigenic determinants were similar to those of the pure preparations before precipitation[23,24]. The electrophoretic behaviour of the glycoproteins on polyacrylamide gels in sodium dodecyl sulphate (SDS) was also unaffected by the precipitation, and, as Fig. 1 shows, none of the three preparations showed detectable contaminant bands when stained for protein or carbohydrate.

Preliminary studies on the size of Thy-1 in the absence
Fig. 1 Purity of Thy-1 fractions analysed by polyacrylamide gel electrophoresis in sodium dodecyl sulphate. B, L+ and L− denote Thy-1 purified from brain, and Thy-1L+ and Thy-1L− from thymocytes respectively, staining for protein with Coomassie blue (*a*) or for carbohydrate with periodic acid–Schiff (*b*) stain[23]. The Thy-1 glycoproteins which had been precipitated with ethanol and solubilised in water, were electrophoresed on 7.5% polyacrylamide gels in SDS[23]. 14 µg and 22 µg of the glycoproteins were loaded for gels stained for protein and carbohydrate, respectively.

of deoxycholate have been carried out by sedimentation equilibrium methods in the ultracentrifuge, and most Thy-1 was in an aggregate of 250,000–350,000 weight-average molecular weight (unpublished results of P. Kuchel). After addition of deoxycholate, Thy-1 was found in an antigen–detergent complex of molecular weight 29,000, in agreement with previous studies[22,24]. Aggregation in the absence of detergent would be expected for a membrane molecule which was normally associated with lipids.

Table 1 Amino acid composition of Thy-1 glycoproteins

| | No. of amino acids per 100 residues | | |
| | Brain | Thymocyte | |
	Thy-1	Thy-1L+	Thy-1L−
Asx	12.7	12.6	13.0
Glx	9.1	9.1	9.1
His	4.1	3.8	4.0
Lys	6.9	7.2	7.0
Arg	7.5	7.5	7.2
Thr	7.6	8.6	8.3
Ser	7.4	7.1	7.9
Pro	3.6	3.8	3.0
Ala	3.3	2.9	3.2
Cys	3.1	3.2	3.2
Gly	6.0	4.9	5.0
Tyr	2.0	2.0	2.0
Val	7.3	7.4	7.4
Ile	3.9	4.1	4.0
Leu	10.4	11.2	11.1
Phe	4.0	3.7	3.8
Met	1.1	0.9	0.8

Amino acid analyses are expressed as the mean number of each amino acid residue per 100 residues and are the result of at least four analyses in each case. For brain Thy-1 and thymocyte Thy-1L+, two completely independent preparations of each were analysed, while for thymocyte Thy-1L− one preparation was used. The amino acids are arranged into hydrophilic, intermediate and hydrophobic groups[25] reading down the table. Samples for amino acid analyses were hydrolysed with constant boiling HCl at 110 °C for 20 h and analysed on a Locarte or modified Beckman analyser[26]. A correction for the destruction of threonine and serine was calculated from 24-and 72-h hydrolyses of Thy-1 from brain and applied to all analyses. Cysteine was estimated as cysteic acid after performic oxidation[27]. The s.e.m. was < 5% of each mean value except for proline values (< 12%).

Chemical analysis of the Thy-1 glycoproteins

The preparations of Thy-1 shown in Fig. 1 were analysed for their amino acid (Table 1) and carbohydrate compositions (Table 2) by standard procedures. The amino acid analyses were very similar for the three forms of Thy-1 and the only differences which were significant after statistical analysis (not shown) were those between the leucine and glycine content of brain Thy-1 in comparison with thymocyte Thy-1. The compositions were so similar, however, that any differences which may exist in the protein part of the molecules will only be clearly revealed by amino acid sequence analysis. If the amino acids are grouped on the basis of their hydrophobicity (Table 1), it can be seen that Thy-1 is much less hydrophobic than some membrane proteins[24] and indeed is notable for its large proportion of hydrophilic residues. Hydrophobicity in amino acid compositions is, however, not an invariable feature of membrane proteins and the major human red cell glycoprotein which is superficially similar to Thy-1 is also quite hydrophilic in its amino acid composition[27]. In detail the amino acid compositions of the red cell glycoprotein and Thy-1 are very dissimilar.

If the molecular weight of 25,000 as determined by electrophoresis on polyacrylamide gels in SDS is taken as correct, then the size of the polypeptide portion would be about 17,000 and the values in Table 1 should be multiplied by 1.5 to give the number of residues per molecule.

In contrast to the amino acid analyses, marked differences in carbohydrate composition were found particularly between brain and thymocyte Thy-1 with smaller differences between thymocyte Thy-1L+ and Thy-1L−. These results are shown in Table 2 and are expressed as residues per 100 residues of amino acids. If the figures are multiplied by 1.5, an estimate of residues per molecule can be obtained. Galactosamine was found only in brain samples and no trace was detected in thymocyte Thy-1. In contrast, sialic acid was present in very small amounts in brain Thy-1, but in much larger amounts in thymocyte Thy-1. The amounts of fucose, glucose and galactose also differed by a factor of 2 or more between brain and thymocyte Thy-1, while smaller differences on a percentage basis were found between mannose and glucosamine contents. Given that differences in composition are likely to reflect much larger differences in structure, the carbohydrate chains of brain and thymocyte Thy-1 may be completely unrelated.

Between thymocyte Thy-1L+ and Thy-1L− the compositions were much more similar, but differences in the amount of galactose, mannose, glucosamine and sialic acid may be significant. These differences in composition do not provide a simple answer as to why Thy-1L− fails to be bound by the lentil lectin, except to reinforce the view that it is likely to be due to differences in the carbohydrate rather than the polypeptide structure. The differences between Thy-1L+ and Thy-1L− are typical of the micro-heterogeneity of carbohydrate residues observed for many glycoproteins[23]. The large differences between brain Thy-1 and thymocyte Thy-1, however, represent a much more unusual order of heterogeneity of carbohydrates and could reflect a similar polypeptide chain carrying unrelated carbohydrate structures in the two tissues.

In the carbohydrate analysis by gas–liquid chromatography only small amounts of material other than known sugars were found; these included traces of lipid (see legend to Table 2). The procedures used in the purification of Thy-1 involving deoxycholate and ethanol would be expected to remove non-covalently-bound lipids and previously no lipid-bound phosphorus (less than 0.05 mg of phospholipid per mg of Thy-1) had been detected in brain Thy-1 (ref. 24).

From a summation of the amino acid and carbohydrate analyses, the percentage composition by weight of the molecules was calculated (Table 2). The values for carbo-

hydrate content of about 30% are higher than for many membrane glycoproteins.

Chemical basis of Thy-1 antigenic determinants

Rat Thy-1, regardless of its tissue origin, carries at least three sets of antigenic determinants. These include Thy-1.1 which is recognised by mouse alloantiserum[8,13] and two xenoantigenic determinants recognised by rabbit serum[9,14]. The similarity between the amino acid compositions, and the differences in carbohydrate compositions of Thy-1 from brain and thymocytes suggest that these antigenic determinants are defined by the protein rather than the carbohydrate structure. To investigate this point further the susceptibility of the antigenicity to heating and proteolysis was studied. Both of these procedures should destroy protein determinants which are usually dependent on conformation[34] but leave carbohydrate antigenic determinants intact[35].

Samples of pure Thy-1 were heated for 10 min at various temperatures and assayed for Thy-1.1 and Thy-1 xenoantigenic determinants (Thy-1 rat specific and rat–mouse cross reacting xenoantigenic determinants were not distinguished). Figure 2 shows a typical experiment in which the activity of these antigenic determinants of brain Thy-1 was destroyed in the temperature range 70–80 °C. Similar results were obtained in experiments with thymocyte Thy-1L+.

The effects of proteolytic digestion were evaluated by measuring the loss of antigenic activity with the inhibition assays, and destruction of the polypeptide chain by SDS–polyacrylamide gel electrophoresis. Thy-1 was quite resistant to all the proteolytic enzymes tested, but after incubation

Temperature (°C) of preincubation
Fig. 2 Effect of heat on the Thy-1 antigenic determinants. The figure shows the results of two experiments on heating of brain Thy-1, assaying for Thy-1.1 (○) and Thy-1 xenoantigenic activities (□). Purified Thy-1 (approximately 10 µg ml⁻¹) was heated for 10 min at the temperature shown in 0.1 % sodium deoxycholate, 0.25 % bovine serum albumin, 0.02 % NaN₃ and 0.01 M Tris-HCl, pH 8.0. The samples were cooled to 0 °C and assayed for Thy-1.1 and Thy-1 xenoantigenic activities[23]. These activities are expressed as the percentage activity compared with a similar sample kept at 0 °C throughout (100 %).

with Pronase for 24 h at 37 °C, 80–95% of the antigenic activity of all Thy-1 determinants was destroyed (**Table 3**). Also the polypeptide chain was almost completely degraded as shown for brain Thy-1 and thymocyte Thy-1L+ in Fig. 3a and b, respectively. Pronase digestion for 3 h caused only partial loss of antigenic activity and partial removal of the polypeptide chain. When brain or thymocyte Thy-1 was incubated for 24 h with trypsin, chymotrypsin or papain (conditions as for Pronase in Table 3 except for the addition of cysteine HCl with papain), there was only partial loss (30–80%) of antigenic activity and the Thy-1 molecule. On a qualitative basis no discrepancies were observed between the amount of antigenic activity and the amount of Thy-1 band remaining on the polyacrylamide gel.

These results, together with the chemical analysis (Tables 1 and 2), and the experiments on the effect of heating, strongly (although not conclusively) suggest that all the antigenic determinants so far identified on rat Thy-1 are expressed by the protein part of the molecule.

Confusion about the nature of the Thy-1 molecule

There has been considerable disagreement about the chemical nature of the Thy-1 molecule. Most other workers have studied mouse Thy-1 but the basic characteristics of the molecule are likely to be similar in both mouse and rat.

Table 3 Effect of Pronase on Thy-1 antigenic activities

| | Residual antigenic activities (%) | |
	Thy-1.1 antigenic activity	Thy-1 xenoantigenic activity
Thy-1 (brain)	3, 7, 6	5, 6, 4
Thy-1L+ (thymocyte)	16, 10, 11	14, 9, 8

Purified brain Thy-1 or thymocyte Thy-1L+ was incubated at 37 °C for 24 h in the presence or absence of Pronase. The antigenic activities of the digested and control preparations were then assayed and are shown for three independent experiments as the percentage of the digested material compared with the control incubation. In the incubation Thy-1 was at 400 µg ml⁻¹ in 0.25 % Na deoxycholate, 0.02 % NaN₃ and 0.01 M Tris-HCl, pH 8.0, and Pronase was added at a weight ratio of 1 : 12 compared with antigen. The assay of antigenic activity was done at 0 °C in the presence of a 1,500-fold excess of bovine serum albumin to inhibit residual Pronase activity.

A glycoprotein band similar to rat Thy-1 can be identified in mouse thymocyte membrane, and the mouse Thy-1.1 antigenic activity is found in the same place as rat Thy-1 after gel filtration in deoxycholate[23]. Also Trowbridge et al., using hyperimmune serum to rat brain Thy-1, could immunoprecipitate a glycoprotein of molecular weight about 25,000 from mouse thymocytes which had been surface labelled with ¹²⁵I and solubilised in detergent[20]. This molecule was present in tissue culture cell lines which displayed Thy-1 antigen, but absent from mutants which had become negative for the antigen[21]. Using conventional anti-(Thy-1) alloantiserum they could not precipitate the 25,000 molecular weight glycoprotein and this confirmed the observations of Vitetta et al.[16]. The latter authors interpreted this to mean that Thy-1 antigens were inactivated by detergent, but this was clearly shown to be incorrect in studies using inhibition of radioimmunoassays[22]. It is more likely that the failure to precipitate Thy-1 was due to low affinity of conventional alloantiserum, leading to dissociation of antigen–antibody complexes in the washing of the immunoprecipitates. In similar experiments Atwell et al.[18] immunoprecipitated a protein of apparent molecular weight 60,000. This result has not been confirmed by others, and may have been due to the use of nonspecific antiserum.

Sauser et al. have suggested that the Thy-1.2 alloantigen is associated with a protein of molecular weight about 40,000 which they obtained in preparations purified 60-fold for the antigen[19]. Thy-1 glycoprotein in the rat was pure when Thy-1.1 antigenic activity was purified 260-fold[23] and thus it is possible that the protein of Sauser et al.[19] is a major contaminant in a fraction which also contains Thy-1 glycoprotein.

Miller and Esselman have suggested that mouse Thy-1 antigen is a ganglioside[17] and this is completely inconsistent with the antigenic determinants being in the protein part of a glycoprotein. Their inhibitions of Thy-1 cytotoxicity assays with gangliosides, however, do not show the high degree of specificity expected for the Thy-1 alloantigens as defined by Reif and Allen[4]. Thus Miller and Esselman suggest that GM₁ ganglioside carries the Thy-1.2 determinant, yet ganglioside from a Thy-1.1 strain inhibits a

Fig. 3 Effect of Pronase on the Thy-1 glycoproteins. The Thy-1 glycoproteins were digested with Pronase as described in Table 3 and the effects analysed by electrophoresis on 7.5 % polyacrylamide gels in SDS (as in Fig. 1). Equal amounts of protein from each digest and its control (about 5 µg) were electrophoresed and after staining for protein with Coomassie blue the gels were scanned at 550 nm[23]. a, Scans for brain Thy-1 control (—) and brain Thy-1 after Pronase digestion (- - -). b, Thymocyte Thy-1L+ control (—) and Thy-1L+ after Pronase digestion (- - -).
cytotoxicity assay for Thy-1.2, 50% as well as ganglioside from a Thy-1.2 mouse[17]. Also, very large amounts of ganglioside were needed for inhibition of the cytotoxicity assay for Thy-1.2, for example for 50% inhibition approximately 500 ng of GM$_1$ (molecular weight 1,500) was required, compared with 10 ng of Thy-1 glycoprotein (molecular weight 25,000) for 50% inhibition of radioactive binding assays for Thy-1.1[13,14]. Finally, other authors have not been able to find Thy-1 antigenic activity in lipid fractions[24,37].

Trowbridge *et al.* agree that Thy-1 is carried by a glycoprotein[20], but have suggested that the antigenic determinants of mouse Thy-1 are on the carbohydrate and not the protein part of the molecule[21]. This view was based on studies on mutant cell lines, but there is no obvious reason why the data cannot be interpreted equally well with the antigenic determinants carried by the protein part of the molecule.

Possible function for Thy-1 in thymus and brain

In mouse, peripheral T cells have Thy-1 and bone marrow cells do not[7], whereas in the rat the converse is true[11]. Thus it is possible that Thy-1 is not of functional significance in these cell types of either species. In thymus and brain, Thy-1 is a major membrane glycoprotein and these are likely to be the tissues in which the Thy-1 molecules have a biological function.

A large part of the protein of the Thy-1 molecule is likely to be exposed at the cell surface since its amino acid composition is hydrophilic and the antigenic determinants are clearly available on intact cells. By analogy with other membranes, the carbohydrate structures are also likely to be exposed[33]. Although there is no evidence about the function of Thy-1, the molecular properties do provide some limitations. For example, if the polypeptide chain mediates the specific function of Thy-1, the functions are presumably the same in both thymus and brain. Alternatively, the specific function may be mediated by the carbohydrate structures. In this case the polypeptide chain may anchor the molecule in the membrane and provide a backbone for the display of different carbohydrate ligands in thymus and brain. Cell surface carbohydrate has been suggested to be involved in cell–cell interactions by providing recognition sites for glycosyl transferases or lectins on other cells[38–40]. These ideas have gained particular emphasis in studies on slime moulds where strain specific lectins have been identified. These are found at the cell surface and may be involved in the aggregation of single cells in the slime mould's life cycle[40,41]. In thymocytes and brain, Thy-1 would be an obvious possibility as a molecule involved in functions of this type. If this is the case, the differences in carbohydrate composition between brain and thymus Thy-1 may reflect differences in the specificities of recognition in the two tissues.

We thank Mr. T. Gascoyne for amino acid analyses; Ms Sheila Lathwell for amino sugar analyses and Ms Marilyn Simpkins for technical assistance. Drs. M. J. Crumpton and D. Snary gave advice on the precipitation of glycoproteins and analysis of carbohydrate. M. L-M. was a centennial fellow of the MRC of Canada and A.N.B. was supported by a UK MRC research fellowship.

Nucleotide rigidity

Frederick E. Evans & Ramaswamy H. Sarma

Department of Chemistry, State University of New York at Albany, Albany, New York 12222

It is shown that in aqueous solution the backbone conformation of adenosine is as much flexible as that of 3'-AMP, 5'-AMP and 3', 5'-ADP indicating that nucleotides are not any more rigid than nucleosides. The flexible conformation of the monomeric components is conserved in the nucleotidyl units of destacked ApA, ApApA and poly(A), but it is not conserved in base stacked conditions. The findings are extended to guanosine, uridine and cytidine systems. It is projected that in aqueous solution, conformations of the individual nucleotidyl units of yeast tRNA^{Phe} are confined to the classically stable domains in the base stacked region and non-rigid flexible structures populate in the unstacked region comprising D16, D17, G20, U47 and A76.

MANY investigations have been carried out on the conformation of mononucleotides in order to understand better the conformation of biologically functional nucleic acids. It has been proposed that the conformation of mononucleotides is rigid, and because of this their conformation is conserved in polynucleotides[1–3]. The essential elements of the concept of a conforma-
ApApA

Fig. 1 Structure of ApApA, showing the atom numbering scheme and notations for the torsion angles (IUPAC-IUB recommendations).

tionally rigid nucleotide[1] are (1) that the nucleotides are conformationally more rigid than the corresponding nucleosides and that the phosphate group imparts rigidity to the nucleotides (this has been termed the 'phosphate effect'[1,2]) and (2) that polymers achieve their biologically functional structure by rotation around the phosphodiester bonds. Quantum mechanical calculations suggested that the intrinsic conformational rigidity of a nucleotide may not be fundamentally different from that of the corresponding nucleoside[3]. The concept of rigidity is based on the finding that in the solid state nucleosides exhibit a constant conformational pattern—glycosidic torsion = *anti*; sugar pucker = ^3E; $\psi \simeq 60°$ and $\phi \simeq 180°$—which is absent in nucleotides[1,2]. Recent X-ray crystallographic studies have found several nucleotides with conformations different from that of a rigid nucleotide[4-9]. Some differences have been found between solid state and solution state conformations[10-12]. We have undertaken a systematic study of the fine conformational features in aqueous solution of adenosine (A), 3'-AMP

(Ap), 5'-AMP (pA), 3',5'-ADP (pAp), ApA, ApApA (Fig. 1) and poly(A) as well as uridine, 3'-UMP (Up), 5'-UMP (pU), UpU and poly(U) using high frequency nuclear magnetic resonance (NMR) spectroscopy combined with a Karplus-type analysis of the coupling constants. Here we examine the results obtained with respect to the rigid nucleotide concept.

All materials used were commercial preparations. ¹H NMR spectra were recorded at 100, 270 or 300 MHz in the Fourier transform mode using systems described elsewhere[13-15]. All NMR spectra were analysed using a UNIVAC 1108 computer and LACON III. The observed and simulated spectra of ApApA is shown in Fig. 2 and the data are summarised in Table 1.

Conformation in destacked oligomer and polymer

The backbone linkage is comprised of the C4'-C5'-O5'-P-O3'-C3' bond network. The conformation of the C4'-C5' and C5'-O5' bonds shows itself in the coupling constant sums $\Sigma(J_{H4'-H5'} + J_{H4'-H5''})$ and $\Sigma'(J_{H5'-P}-J_{H5''-5})$ respectively[18]. The near identity in the values of Σ(Table 1, Fig. 2) for each of the adenylyl parts in mostly destacked ApApA (72 °C) clearly shows the strong similarity in the time-average conformation about the three C4'-C5' bonds. The Σ data in Table 1 further reveal that this C4'-C5' bond conformation is very similar to that in mostly destacked ApA (72 °C) as well as to that in 3',5'-ADP, 3'-AMP, 5'-AMP and adenosine. Likewise, the Σ' data in Table 1 reveal that the conformational preference about the C5'-O5' bonds in destacked ApApA and ApA is strongly similar to that of the same bonds in 5'-AMP and 3',5'-ADP. The observed values of Σ and Σ' can be translated into an estimate of the percentage population of conformers using empirical equations developed in this laboratory[18]. These equations have been recently modified[19]. Computation of the population distribution of conformers shows that the *gauche-gauche* (ψ, ψ_1, ψ_2, $\psi_3 = 60°$) population is 70–80%, and the combined population of *gauche-trans* (ψ, ψ_1 ψ_2, $\psi_3 = 180°$) and *trans-gauche* (ψ, ψ_1, ψ_2, $\psi_3 = 300°$) conformers is 20–30% irrespective of whether one is dealing with a nucleoside, 3'-nucleotide, 5'-nucleotide, 3'5'-diphosphonucleoside or a destacked dinucleoside monophosphate or a trinucleoside diphosphate. The *gauche'-gauche'* (ϕ, ϕ_1 ϕ_2 $\phi_3 = 180°$) population about C5'-O5' for all these compounds lies between 65–75%. The observed time-average preference for the *gauche-gauche* and *gauche'-gauche'* arrangement is further substantiated by the 1.5–1.8-Hz magnitude of the four-bond $^4J_{H4'-P5'}$ coupling [20].

Information on the conformation about the C3'-O3' part of the backbone can be obtained from the magnitude of the coupling constant $J_{H3'-P3'}$ (refs 15 and 21). The observed

Concentration is 0.02 M for ApA and ApApA, pD 7.0. Concentration is 0.05 M for the mononucleotides, pD 5.4. The pD is such that the phosphate will be mostly monoanionic like the oligomers and polymers. Data for the monomers at 22 °C can be compared with data for oligomers and polymers at higher temperatures because at the concentration used, the monomer conformations are not significantly perturbed in the temperature range. See, for example, data for 5'-AMP at 22 °C in D₂O and at 86 °C in DMSO-D₂O. Error in coupling constants ±0.1 Hz unless otherwise stated.
* The assignments for the three 1' resonances proposed by Kondo *et al.*[16] has been verified by the incremental methods of Tso' *et al.*[17] by comparing ApA, ApApA and ApApApA.
† Poly(A) dissolved in 50% d₆-DMSO and 50% D₂O at 86 °C, 0.05 M in mononucleotide. For error in the analyses see legend of Fig. 4.
‡ These values are approximate because of the presence of extensive second order perturbations at the frequency used of 270 MHz.

values of $J_{H5'-P3'}$ indicate that in the component monomers, as well as the dimer and trimer at 72 °C, the C3'–O3' bonds have similar time-average conformations.

The ribofuranose ring conformation in nucleic acids and their components in aqueous solution may be treated as a simple C2'-*endo* (²E) and C3'-*endo* (³E) equilibrium[22,23] or as an equilibrium of entities with precise phase angles and amplitudes of pucker[24]. The pseudorotational approach[24] is a major improvement over the classical description for solid state data. However, for the majority of nucleotide systems in aqueous solution the pseudorotation approach may not be sufficiently accurate to be an improvement over the simple qualitative approach of a ²E ⇌ ³E equilibrium[23,24]. The percentage population of ³E conformers in adenosine, 3'-AMP, 5'-AMP, 3',5'-ADP, ApA 72 °C, ApApA 72 °C were computed (Fig. 3*a*) and the data show that the component monomers, irrespective of whether a nucleoside or a nucleotide, have the same time-average conformation for the ribose ring. These are only slightly different from that of ApA 72 °C and ApApA 72 °C. Later discussion will show that the ApA and ApApA ribose rings did not approach the same conformational distribution of the components because at the temperature used (72 °C both ApA and ApApA display a certain degree of stacking in D₂O (refs 27, 28).

Two conclusions emerge from the data: (1) In the adenosine series, in aqueous solution the nucleoside and the nucleotides have the same time-average conformation with respect to the ribose ring, the C5'–O5', C4'–C5' and C3'–O3' bonds. It does not seem therefore, that this part of the nucleotide backbone is conformationally more rigid than in nucleosides, at least for the system investigated. The observation that the phosphate group present at the 3' or 5' position or at both the positions

has no detectable effect on the population distribution of conformers about C4'–C5', C5'–O5', C3'–O3' and the ribose ring argues against an effect of the phosphate group on conformation. The mononucleotide components 3'-AMP, 5'-AMP and 3',5'-ADP essentially conserve their backbone conformation as they become integrated into the framework of the destacked oligomers ApA and ApApA.

It is of interest to determine whether these conclusions can be extended to the case of a polymer such as poly(A). The spectrum of poly(A) in the destacking solvent DMSO/D₂O at 86 °C was taken and the entire spectrum was computer simulated (Fig. 4). The extracted values for Σ, Σ' and $J_{H3'-P3'}$ (Table 1) as well as the computed percentage of ³E population (Fig. 3*a*) clearly reveal that destacked poly(A) has a time-average backbone conformation very similar to that of the component monomeric units.

Conformation in the stacked oligomer and polymer

The discussion presented shows that the monomeric units conserve their preferred conformation for the backbone in the destacked oligomer and polymer. This is not true in the case of stacked molecules. Comparison of the computed percentage populations of ³E conformers for stacked poly(A), ApApA and ApA (low temperature in D₂O) with that for the component monomers (Fig. 3*b*) reveals that the ribose ring in the mostly stacked oligomers and polymer displays a conformational preference dramatically different from that of the monomeric components. The ³E populations in the monomers are about 40%, while the corresponding populations for ApA, ApApA and poly(A) in conditions which favour stacking lie in the
Fig. 3 *a*, Computed percentage populations of the ³E ribose conformers in monomers and in mostly destacked ApA, ApApA and poly(A). *b*, Computed percentage populations of the ³E ribose conformers in monomers and in mostly stacked ApA, ApApA and poly(A). The populations are computed by the method described elsewhere (ref. 15, and F. S. Ezra, C. H. Lee, N.S. Kondo, S. S. Danyluk, and R.H.S.). This method enables us to calculate %³E or %²E populations from either $J_{3'4'}$ or $J_{1'2'}$ using an empirical sum of $J_{1'2'} + J_{3'4'} = 9.5$ Hz. This sum was derived from 30 ribose units of 15 different dinucleoside monophosphates (ref. 15, and F. S. Ezra, C. H. Lee, N. S. Kondo, S. S. Danyluk, and R.H.S.). In the crystals of ApApA, the ribose assumes ³E pucker[26]. The abbreviations A, Ap and pA refer to adenosine, 3'-AMP, 5'-AMP and 3', 5'-ADP. The percentage population of ²E conformer = 100 − %³E.

range of 60–80%. The higher end of the range is preferred by the central –pAp– unit of ApApA and the nucleotidyl units in poly(A). It should be stressed that as the monomeric components become integrated into the framework of a biologically functional stacked polymer, not only is there a significant increase in the populations of ³E conformers, but also there is a shift in the kind of pucker they prefer, that is, the monomers prefer ²E sugar pucker ($\simeq 60\%$) but the oligomers and polymer prefer ³E sugar pucker. Mononucleotides do not conserve their isolated individual conformations as they become part of a polymer in the case of base-stacked adenyl polynucleotides. The low temperature ApApA and poly(A) spectra are extremely complex and so cannot be completely analysed to obtain the values for $J_{H3'-P3'}$, Σ and Σ′. However inspection of the data in Table 1 for 3'-AMP, 5'-AMP, 3', 5'-ADP and ApA (12 °C) shows that stacking significantly changes the conformational preference about the C5'–O5' bond of the –pA unit. On the basis of the temperature dependence of Σ and Σ′ values in ApA, we have previously suggested that the C4'–C5' and C5'–O5' bonds are predominantly *gauche–gauche* in the totally base-stacked state[29].

Conformation in oligo- and polynucleotides other than the adenosine family

Published ribose coupling constant data[12,30,31] on guanosine, 3'-GMP and 5'-GMP in aqueous solution clearly reveal that the nucleosides and the nucleotides display similar distribution of ²E and ³E conformers. The Σ values[12,30,31] show that in all three cases the percentage population of the *gauche–gauche* (ψ = 60°) conformer about C4'–C5' is about 70–75%. Unusual line broadening complications prevent the analyses of the ¹H NMR spectra of GpG and GpGpG and one cannot at present determine the conformational status of the guanosine nucleotidyl units in the oligomer.

Single-stranded polypurine nucleotides are known to exhibit considerably more base stacking than poly(U) in aqueous solution. The coupling constant data for 3'-UMP, 5'-UMP, UpU and poly(U) (Table 2) are, within error limits, similar in their magnitudes, which indicates that in aqueous solution at room temperature the backbone conformation of poly(U) is as flexible as that of the constituent mononucleotides, unlike the case in the adenyl series discussed earlier.

Table 2 Coupling constant data for the various nucleic acid systems of the uridine family

Coupling nuclei	Uridine	3′–UMP	5′–UMP	UpU Up–	UpU –pU	poly(U)*
H1′–H2′	4.4	5.0	4.8	4.2	3.9	5.5
H2′–H3′	5.3	5.2	5.0	5.2	5.1	5.5
H3′–H4′	5.5	5.2	4.3	5.3	5.0	4.0
H3′–P3′	–	8.2	–	8.2	–	9.0
H4′–H5′	3.0	2.8	2.4	2.4	2.4	–
H4′–H5″	4.4	4.2	2.8	4.0	3.2	–
Σ	7.4	7.0	5.2	6.4	5.7	7.5
H4′–P5′	–	–	2.1	–	2.0	–
H5′–P5′	–	–	4.3	–	4.4	–
H5″–P5′	–	–	5.1	–	4.5	–
Σ	–	–	9.4	–	8.9	8.0
H5′–H5″	–12.7	–12.8	–11.7	–13.1	–11.9	–12.5

The concentration is 0.05 M for the monomers. The pD of 3′–UMP and 5′–UMP solutions were kept at pD 5.4 so that the phosphate will be mostly monoanionic like the oligomers and polymer at pD 7.4. For UpU concentration 0.02–0.03 M, pD 7.4. The temperature in all cases was 22 °C. Error in coupling constants ±0.1 Hz unless otherwise stated.
*From ref. 32.

Comparison of the values of $J_{H3'-H4'}$ in uridine and 5′–UMP indicates that this coupling constant undergoes a reduction of 1.2 Hz on phosphorylation at the 5′ position. This translates into an increase of about 15% in the population of ^3E conformers for the ribose ring on 5′ phosphorylation. Equally interesting is the observation that the value of Σ decreases by 2.2 Hz on 5′ phosphorylation of uridine, indicating that the presence of the phosphate group increases the *gauche–gauche* (ψ = 60°) populations about C4′–C5′ by a substantial 20–25%. These observations in the uridine series are very different from those of the adenosine and guanosine series and agree with the projections of a conformationally rigid nucleotide[1,2]. Comparison of the coupling constant data for cytidine, 3′–CMP, 5′–CMP and CpC in Lee *et al.*[15] indicate that in the cytidine series, as in the uridine series, the 5′ nucleotide is conformationally more rigid than the nucleoside; but unlike the uridine system, the mononucleotide conformation is not conserved in the dimer.

Relevance to tRNA conformation

From the foregoing discussion it is clear that the conformational properties of common nucleic acid components, oligo- and

Fig. 4 100 MHz Fourier transformed ^1H-(^{31}P) spectrum of poly(A) in 50% d_6-DMSO and 50% D_2O at 86 °C, 0.05 M (top) and the computer simulation (bottom). The extracted coupling constants from simulation are only accurate ±0.5 Hz because of line broadening complications. It should be pointed out that the accuracy would be considerably less if phosphorus decoupling had not been used.
polynucleotides in aqueous solution are not governed by a common principle such as the concept of a conformationally rigid nucleotide[1,2]. On the one hand in the adenosine and guanosine series, the backbones of the nucleosides and nucleotides are equally flexible, but on the other hand in the uridine and cytidine series, the nucleotides are relatively less flexible than their corresponding nucleosides. The concept that the conformational destiny of mononucleotides, as they become part of polynucleotides is ordained by their intrinsic conformations and that they maintain their isolated conformations in the polymer, is true when significant amounts of the polymer are in the destacked state. This is analogous to the solution conformations of coenzyme A and nucleoside diphosphohexoses which exist as a blend of mostly unfolded and folded conformers[14,21]. The conformational conservation breaks down as soon as the mononucleotides become integrated into the backbone framework of a biologically functional base-stacked polynucleotide. The nucleotidyl units in a base-stacked oligomer and polymer exhibit backbone conformations significantly different from the individual conformations of the monomeric components in aqueous solution.

Even though our findings seem to support the reported presence of non-rigid nucleotides in tRNA[33], we wish to examine our results with regard to the sophisticated structure of yeast phenylalanine tRNA derived by Sussman and Kim[34] by examination of the common features from three sets of atomic coordinates. These authors report the presence of extensive base stacking along the central core of the two molecular axes, that is, the amino acid arm and TψC arm make one axis and the dihydrouridine arm and the anticodon arm the other. The bases that are not stacked are D16, D17, G20, U47 and A76. Assuming that the structure of yeast tRNA[Phe] in crystals is the same as that in solution[35–38] from the present findings one may project that in the fully base-stacked regions of tRNA[Phe] in aqueous solutions, the sugar-base torsion will occupy the *anti* domain, the ribose ring a ^3E pucker, the C3′–O3′, C4′–C5′, C5′–O5′, O3′–P and O5′–P preferring domains centred around φ′ ≃ 210°, ψ ≃ 60°, φ ≃ 180°, ω′ ≃ 300° (≃ 60°) and ω ≃ 300° (≃ 60°). The present data do not enable us to make a distinction between right-handed stacks (ω′/ω = 300°/300°) and left-handed loop stacks (ω′/ω = 60°/60°), even though ω′/ω = 60°/60° stacks are expected only in the loop region. One would expect the unstacked region comprising[34] D16, D17, G20, U47 and A76 to show conformational freedom and flexibility so much so that alternative conformers such as ^2E, ψ ≃ 180°/300° become allowed. Because of the demonstrated conformational nexus in aqueous solution among sugar–base torsion, sugar-pucker, C3′–O3′ torsion and ω′/ω rotations (refs 15, 39; F. S. Ezra, C. H. Lee, N. S. Kondo, S. S. Danyluk, and R. H. S., unpublished, and D. M. Cheng and R. H. S., unpublished) one would also anticipate that those fractional populations which exist in ^2E conformations in the unstacked region will also populate in domains in which ω′/ω ≃ 180°/300°, φ′ ≃ 270° and the value of χ, though still in the *anti* domain, several degrees above the ones encountered in the base stacked region. Our general conclusion is that in aqueous solution, conformations of the individual nucleotidyl units of yeast tRNA[Phe] are confined to the classically stable domains, as has been reported in crystals by Sussman and Kim[34] and that non-rigid flexible structures are confined to that region of tRNA which is not base stacked.

Detection of hot gas in clusters of galaxies by observation of the microwave background radiation

THE Uhuru (ref. 1) and the Ariel V (ref. 2) satellites have shown that many rich clusters are powerful sources of X rays. This emission has been interpreted either as thermal bremsstrahlung of very hot gas filling the clusters[3,4], or as inverse Compton scattering of photons by relativistic electrons[5,6]. Spectral evidence[2] has begun to favour a thermal origin for this radiation, implying the existence of large amounts of hot gas. Such gas would have a profound influence upon the dynamics of radio sources, and its mass might well be a substantial fraction of that of the whole cluster. Hot gas may therefore be a major constituent of the Universe, so that independent confirmation of its existence is extremely important. We present here observations of small diminutions in the cosmic microwave background radiation in the directions of several rich clusters of galaxies. This confirms the existence of large amounts of very hot gas in these clusters and indicates that their X radiation is thermal bremsstrahlung and not inverse Compton emission.

A necesary consequence of the existence of hot gas in clusters is the Compton scattering of the cosmic microwave background by hot electrons[7]. As a result, some of the microwave photons are redistributed with slightly higher energies, and the effect may be observed at radio frequencies as a small diminution in the background temperature. The magnitude of this effect is predicted to be $\sim 0.5 \times 10^{-3}$ K for the gas clouds associated with cluster X-ray sources ($\rho_{gas} \simeq 5 \times 10^2$ atom m^{-3}, $T_{gas} \simeq 2.5 \times 10^8$ K, $l \simeq 300$ kpc (refs 4, 7)). Parijskij[8] has claimed to have detected this effect at a slightly higher (1.2×10^{-3} K) level in the direction of the Coma cluster, but his result was marginal and in any case seems to have been implicitly withdrawn[9].

We present the first results of an attempt to detect this effect, using the 25-m telescope at the Chilbolton Observatory of the SRC Appleton Laboratory. We have observed 7 clusters, of which 6 are known to be X-ray sources. The remaining cluster (A2218) is very distant, so that no strong limits to its X-ray flux are available. It was included because it is a very rich cluster (richness 4 on Abell's scale) and was known not to contain any non-thermal radio sources likely to mask a diminution in the intensity of the microwave background.

The Coma cluster (A1656) was included, although it is confused by the weak radio source 5C4.85 (36 ± 6 mJy at 10.6 GHz), for which a small correction has been made. Upper limits on the radio flux density from the other clusters are < 100 mJy at 1,400 MHz, though A478 is only 43' distant from the bright radio source 3C109 and no limit on its flux density has been published.

To minimise the effect of non-thermal background sources, it is desirable to observe at the highest possible frequency compatible with atmospheric stability. A frequency of 10.6 GHz was chosen, at which the Chilbolton aerial has a half-power beamwidth of 4.5'. Observations were made using a twin-beam system, the beams being separated on the sky by 14' in the azimuthal direction, which is just sufficient to take the reference beam beyond the central regions of the largest cluster (Coma). Ideally, the beams should be more widely separated than this, but atmospheric irregularities and distortion of the off-axis beam then become severe problems. The receiver included an uncooled one-stage parametric amplifier, having a noise temperature of ~ 280 K and a bandwidth of ~ 200 MHz. The output time constant was 1 s and samples were taken at 0.5-s intervals. The two beams were alternately directed at the centre of a candidate cluster for 20 s at a time; after a complete cycle the mean (x_i) and standard error (σ_i) of the 80 samples (~ 20 independent samples) were stored on-line in a Ferranti ARGUS 500 computer. This 'wagging' procedure was continued until, at the end of an allotted observation period (~ 4 h), the cumulative mean and s.d. were derived, weighting the individual observations by $1/(\sigma_i^2 + x_i^2/2)$ This latter term proved to be an effective gate against spurious high-significance measurements, caused by either atmospheric irregularities with time scales ~ 1 min, receiver drift, or occasional interference from radar. The system was calibrated at regular intervals by injecting a known noise signal into the main beam. The antenna temperatures measured in this way were then converted into equivalent sky temperatures, using radio sources of known flux density and the measured beamshape to determine the aerial efficiency (55%). We have also attempted observations using drift scans. This method is, however, particularly sensitive to atmospheric irregularities and was abandoned in favour of the wagging technique.

The results are given in Table 1. They represent a total of 674 h of observations in 12 weeks during 1975 Nov–1976 June. They show the temperature of background radiation in the directions of the centres[10] of the 7 Abell clusters, relative to a

Table 1 Data obtained

Cluster	Temperature ($\pm$ s.d.) (10^{-3} K)	$\sqrt{\chi}(^2-\sqrt{})n-1$
A376	-0.13 ± 0.66	1.75†
A478	$+0.33\pm0.52$	-1.09

A2319	-0.13 ± 0.41	0.38
A2666	-0.27 ± 0.35	0.42
Blank Sky	-0.01 ± 0.32	-0.39

*Combination of two different positions (see text).
†Slightly discordant.

peculiarly weighted mean of the temperature over arcs 14' on each side of the centre. Each value is the result of many observation periods, and statistical tests have shown that the data are generally concordant and conform rather well to the expected Gaussian distribution. All results have $\sqrt{\chi^2}-\sqrt{(n-1)}<2$, where n is the number of observation periods, so that considerable reliance can be placed on the final standard errors. The result for the Coma cluster is the weighted mean of two different positions, one of which is coincident with the centre of the cluster ($\alpha = 12$ h 57 min 24 s, $\delta = 28°15'$) and is only 3.16' from 5C4.85. A correction of $-1.35\pm0.25 \times 10^{-3}$ K has been calculated from the measured beamshape and flux density of 5C4.85 and applied to this result. No significant correction is required for the second position ($\alpha = 12$ h 57 min 37 s, $\delta = 29°13'$). For comparison, the uncorrected average value for coma is $-1.02 \pm 0.40 \times 10^{-3}$ K. The 'blank sky' observation was included to guard against the possible existence of systematic errors. The value shown is the weighted mean of three different positions, each chosen to have the same declination as either A576 or A2218, thereby ensuring that the observing conditions were nearly identical to those prevailing for the clusters themselves. No evidence of systematic errors was found. At our observing frequency, confusion from non-thermal background sources is expected to be $\sim 0.1 \times 10^{-3}$ K (J. V. Wall, personal communication).

It will be seen that, apart from A478, the results are in the expected sense and amount to a marginal detection of the expected diminutions at the predicted level of 0.5×10^{-3} K. The formal probability of obtaining results of this significance merely by chance is low, as may be seen from the value of χ^2 ($\chi^2 = 30.0$) for all 7 clusters assuming that the effect is absent. With 7 degrees of freedom, this indicates that the results are inconsistent with the assumption of zero mean at the 99.99% confidence level. This test takes no account, however, of the relevant fact that 6 out of 7 results are in the same sense. A further test is the value of the weighted mean of all the clusters, which is $-0.63\pm0.17\times10^{-3}$ K. It must be realised that this figure is only relevant as a test of the null hypothesis and has no particlur astrophysical significance. It should also be emphasised that no data have been rejected and that Table 1 is a complete list of clusters for which we have results. Bearing this in mind, it is clear that the results are most encouraging, if not yet entirely conclusive. Observations with greater sensitivity are now proceeding, in an attempt to confirm the effect at a higher confidence level, and to measure the shape of the diminution for one cluster.

These observations therefore strongly suggest the presence of hot plasma ($> 10^8$ K) filling clusters of galaxies. It seems highly prob·' 'e that the X radiation from these clusters is just the therm.' ·· ‑ahlung of this gas, and that previous inverse Compton interpretations can now be ruled out. Confirmation of these effects will also show directly that the microwave background radiation is truly cosmic, and must have its origin beyond distant clusters of galaxies.

Visibility of galaxies

IT is well known that our counts of galaxies could be seriously biased by selection effects, largely determined by the brightness of the night sky. To illustrate this, suppose the Earth were situated near the centre of a giant elliptical galaxy, then the mean surface brightness of the sky would appear some 8–9 mag brighter than is observed from our position in the Galaxy (~ 23 V mag (arc s)$^{-2}$ looking toward the galactic pole, discounting atmospheric and zodiacal contributions[1,2]). Optical astronomers would then find extragalactic space an empty void; spiral and irregular galaxies would be quite invisible and all they would easily detect of galaxies would be the core regions of ellipticals very similar to their own. They would be blinded to much of the Universe by the surface brightness of their parent
Fig. 1 Central surface brightnesses S_0 of exponential disks of spiral and irregular galaxies taken from Freeman[2] plotted against galactic type. Filled circles show most reliable data, open circles less reliable. Some of the original points, subsequently shown to be incorrect (K. C. Freeman, personal communication) have been removed. (— — — —) is at 21.65 B mag (arc s)$^{-2}$.

galaxy. But this blinding is clearly a relative matter and we should ask to what extent we are blinded by the spiral galaxy in which we exist, faint as it may appear by comparison. I will argue that strong indirect evidence already exists that our knowledge of galaxies is heavily biased by the sky background, and that the true population of extra-galactic space may be very different from the one we can see.

Begin by recalling two sets of observations applying to spirals and ellipticals respectively, that have been in the literature some time. Both are based on de Vaucouleurs' discovery[3] that the radial surface brightness distribution $\sigma(r)$ of galaxies (apart from second order effects like spiral arms) can be described by the law

$$\log_{10}\left[\frac{\sigma(r)}{\sigma(0)}\right] = -\left(\frac{r}{\alpha}\right)^{1/\beta} \qquad (1)$$

where α is a scale-length and $\beta = 1$ for spirals and 4 for ellipticals. Using equation (1) one can show that the total luminosity L_T is

$$L_T = L(r\rightarrow\infty) = \int_0^\infty 2\pi r \sigma(r)\,dr = \frac{(2\beta)!}{(\log_e 10)^{2\beta}}\,\pi\sigma(0)\alpha^2 \qquad (2)$$

In 1970 Freeman[2] collated the best photometry then available for spiral and irregular systems and found the surprising result that $\sigma(0)$ was virtually constant for the disks of all but a few
galaxies in the sample. If we express $\sigma(0)$ in B mag (arc s)$^{-2}$ and then write it as S_0, then Freeman finds $\langle S_0\rangle_s = 21.65 \pm 0.3$ (see Fig. 1).

Fish[4] had earlier discovered an apparently unrelated fact about a sample of well studied ellipticals: he showed that their binding energy Ω varied as $M^{3/2}$ where M is their mass. Fish actually measured L and α for his sample, and then assumed that ellipticals generally have the same mass to light ratio. Disentangling the directly measured quantities from the assumptions

$$\frac{\Omega}{M^{3/2}} = \text{const} \rightarrow \frac{GM^2}{RM^{3/2}} = \text{const} \rightarrow \frac{L_T^{1/2}}{R} = \text{const}$$

But R (the radius) $\sim \alpha$ so, using equation (2), Fish's law implies that

$$\frac{L_T}{\alpha^2} \sim \sigma(0) = \text{const}$$

for the ellipticals in his sample, which comprised most of the best studied individuals at that time. Fish's raw data, not plotted in his paper, are shown in Fig. 2, and we see that Fish's law is conceptually identical with Freeman's, and can be stated thus: well studied bright ellipticals have a central surface brightness $\langle S_0\rangle_E = 14.80 \pm 0.9$ B mag (arc s)$^{-2}$.

When the two laws are placed contiguously in this fashion one begins to suspect that observational selection is responsible, though one is puzzled by the large discrepancy in $\langle S_0\rangle_s - \langle S_0\rangle_E = 6.85$ mag between the two galactic types. I now argue that observational selection can indeed account for both Fish's and Freeman's results rather simply, and even supplies the two different values of $\langle S_0\rangle$ with few assumptions beyond equation (1), which is well tested.

Fish's and Freeman's sample comprise the major proportion of galaxies for which careful surface photometry existed at that time. What criteria are used in selecting galaxies for this type of investigation? De Vaucouleurs[5] has discussed this matter but there is no clearcut answer and, historically, apparent size, apparent area, apparent luminosity and surface brightness have probably all been important. The selection has, however usually, been based initially on photographic material. Because of the limited dynamic range of emulsions the real luminosity is not well measured, and to a first approximation at least, galaxies with large angular radii or areas will generally appear most luminous on a photographic plate. (The belated discovery of Zwicky's compacts, many of which are highly luminous, testifies to this natural selection effect.) Our hypothesis is that it is the apparent radius r_{ap} (and area r_{ap}^2) which gives a galaxy a spectacular appearance on a plate, and makes us believe that it is probably luminous and suitable for more detailed investigation. On this hypothesis the galaxies in the Fish–Freeman samples were therefore probably chosen, consciously or otherwise, mainly for their apparent radii and areas in photographic surveys.

For constant L_T and S_L (where S_L is the limiting surface brightness out to which diffuse objects are readily apparent on a photographic plate) intuition leads one to expect that r_{ap} will have a maximum as $\sigma(0)$ varies. If $\sigma(0)$ is low, even the central isophotes will lie close to σ_L and r_{ap} will be small; conversely, if $\sigma(0)$ is high, then by equation (2), α and hence r_{ap} will also be small.

If σ_L is the limiting surface brightness corresponding to S_L (where S_L is σ_L expressed in magnitudes) then equation (1) becomes

$$\log_{10}\left[\frac{\sigma_L}{\sigma(0)}\right] = -\left(\frac{r_{ap}}{\alpha}\right)^{1/\beta}$$

Then:

$$r_{ap} = \alpha(0.4)^\beta (S_L - S_0)^\beta \qquad (3)$$

Using equation (2) to eliminate α from (3) we obtain

$$r_{ap} = KL_T^{1/2}\left[\frac{1}{\pi 2\beta!}\right]^{1/2} (0.4\log_e 10)^\beta \exp(0.46\,S_0)(S_L - S_0)^\beta \qquad (4)$$

where K is a normalising constant whose value can be obtained from any well studied galaxy, elliptical or spiral. Using NGC3379 (refs 5, 6) with r_{ap} in kpc and L_T in units of $10^9 L_\odot$, $K = 1.20 \times 10^{-4}$ and the results are plotted in Fig. 3. As anticipated there are well defined maxima in r_{ap} for the two types of galaxy. What is surprising is that the $S_0(r_{ap} = \text{max})$ are separated for the spirals and ellipticals by 6.52 mag, which is in the right direction and

very close to the precise size required to explain both Fish and Freeman's laws. Moreover, since for most plate material of interest here, S_L must be close to[7] 24 B mag (arc s)$^{-2}$, then $S_0(r_{ap} = max) = 21.83$ for spirals and 15.31 for ellipticals, so the absolute values are close to those observed as well. Furthermore the scatter in the spiral $S_0(r_{ap} = max)$ would be smaller than for ellipticals as the observations demand. There are no free parameters in Fig. 3 for the β follow from equation (1) and L_T changes only the vertical scale (see equation (4)). It is important to note that L_{ap}, where L_{ap} is the apparent photographic luminosity, also has a double peaked distribution similar to r_{ap} in Fig. 3, but the details are complex and for brevity we omit discussion of L_{ap} here.

What is one to make of the uncanny fit of Fish's and Freeman's data to equation (4)? Conservatively, one could argue that their data are not representative and that the fit is an unlikely coincidence, but a coincidence none the less. Though this could well be correct it is not an heuristically useful hypothesis and we pursue it no further here.

The alternative is to accept our hypothesis, and acknowledge that surprisingly powerful selection effects are involved in picking out galaxies which are apparently large and apparently luminous, and that only objects with a very narrow range of σ(0) will be so selected. If this is true, and only further observations can prove it to be so, then it is likely that our present knowledge of the galactic luminosity function is seriously in error, in that galaxies of all luminosities with σ(0) different from
Fig. 3 Apparent radii r_{ap} (solid lines) and areas πr_{ap}^2 (dashed) for ellipticals and spiral disks of total luminosity $L_{pg} = 10^9 L_{\odot pg}$, as a function of $(S_L - S_0)$. Radius scale on left, area on right. Changing L varies only the vertical scale. The scale under the abscissa is based on the assumption that $S_L = 24$ B mag (arc s)$^{-2}$.

the Fish–Freeman values will be under-represented. Stated thus the hypothesis is hardly new. At one end of the scale Zwicky's work has revealed the hitherto unsuspected compacts while Arp[8], for instance, has demonstrated that the log L/log r plane is everywhere populated where it is detectable, and that there are no good reasons for believing that lower surface brightness objects, and parts of objects, do not exist. Fish's and Freeman's laws are then strong, but indirect evidence for this hypothesis.

On this hypothesis galaxies are like icebergs and what is seen above the sky background may be no reliable measure of what lies underneath. An apparently insignificant dwarf may be the core of a large galactic system of either type. The resolved Sculptor/Fornax systems have S_0 as low as 25 B mag (arc s)$^{-2}$ so the whole range of S_0 between 25 and 15 could be populated. Conceivably the missing mass in groups, clusters and the Universe may be accounted for in this way.

To test the selection hypothesis it will be necessary to move away from the narrowly selected range of objects with spectacu-

lar apparent radii. In a given region of sky all objects suspected to be non-stellar will have to be studied in detail. Since galaxies often contain both elliptical and exponential components it will be necessary to measure both S_0 and α for each component before L_T can be established.

Such a systematic attack could take years. In the shorter term it is interesting to wonder if some few icebergs may be turned up by more *ad hoc* approaches:

(a) Figure 3 reveals that the most dramatic gradient in r_{ap} occurs for spirals with small $S_L - S_0$. The S.R.C. IIIaJ survey should have a deeper S_L than the IIaO and in some cases faint spirals on the IIaO should show a dramatic increase in r_{ap} in going to the IIIaJ.

(b) The cores of both spirals and ellipticals commonly obey the de Vaucouleurs elliptical law. Insignificant-looking ellipticals may sometimes be the tips of giant low-σ(0) spirals which should therefore contain hydrogen. A quick 21-cm survey of a large number of dE might be interesting since Fisher and Tulley's sample[9] contains few dE (dwarf ellipticals).

(c) Although the spiral and H II regions of a galaxy generally represent only a small fraction of the total light, they do have a higher contrast against the night sky. Deep Schmidt plates at wavelengths designed to enhance this contrast (for example Hα) may show some spiral arms with no underlying disk. Ring galaxies may be objects of this type.

(d) Some systems show signs of tidal interference with no apparent cause. 'Dwarfs' in the vicinity warrant careful examination.

(e) Galaxies are often a composite of the two types. Take a disk with $S_0 = 21.65$ mag and add to it an elliptical component with the same S_0 and L_T; equation (4) gives the elliptical r_{ap} as 7% of the disk r_{ap} and so the core will appear insignificant, though it represents the tip of a massive halo. It may be possible to detect such halos by careful measurement of the core scale-length.

(f) Double radio sources with 'empty fields' may sometimes have at their centre a giant galaxy of low S_0, which may be detectable with careful photometry.

In opposition to the selection hypothesis in its most radical form we should point out that σ(0) is not likely to be independent of the total mass, M, of the galaxy, and the giants (that is high mass objects) will in general have a higher σ(0) and will not be so easily missed. But if we suppose that M and $\bar{\rho}$ are the important physical parameters for classifying galaxies then on dimensional grounds σ(0) ~ $M^{1/3}\bar{\rho}^{2/3}$. σ(0) for a giant of $10^{11}M_\odot$ will then in general be less than 3 magnitudes higher than for an extreme dwarf of $10^8 M_\odot$ which is a small difference compared to the total observed range of S_0 between ~8 for extreme compacts[10] and 25 for Sculptor–Fornax systems, so this is probably not an important effect.

Observations are urgently required to determine how important surface brightness selection may be.

I am most grateful to Ken Freeman for many stimulating and instructive conversations.

Trends in the climate of the North Atlantic Ocean over the past century

THE dominant large scale phenomena determining the climate of the North Atlantic Ocean are the current systems of the Gulf Stream and the North Atlantic Drift as well as the pattern of atmospheric circulation associated with the semi-permanent centres, the Iceland low and the Azores high. Recently, three long time series of data have become available which throw some light on the interactions between these ocean–atmosphere systems and which appear to indicate the importance of advective processes, as opposed to upwelling, in determining long term variations in the surface temperature of the ocean.

Interactions between the ocean currents and the atmospheric circulation have been studied by Brooks[1] and subsequently by Bjerknes[2]. The latter postulated that long-term fluctuations in the sea-surface temperature of the North Atlantic were determined by such interactions and, in particular, that periods of low sea-surface temperature corresponded with periods of intensification of the Iceland low and the Azores high and, hence, of the mid-latitude westerly winds. The increased wind was assumed to produce an intensification of the flow of the Gulf Stream. Bjerknes considered that a drop in surface temperature of the northern North Atlantic may be attributed to upwelling

produced by increased cyclonic wind-drag and also to an increase in the cold winds from North America. Working with data from the North Atlantic weather stations from 1952 to 1965, Rodewald[3] has confirmed that cooling of the surface waters of the ocean is associated with an intensification of the atmospheric circulation.

The three long-time series of data referred to above are :

(1) Data for sea-surface temperature, based largely on observations from ships in transit, are held in the marine data deck of the US National Climatic Centre. Monthly means of sea-surface temperature for each 5° × 5° quarter of Marsden squares 145 and 182 (see Fig. 1) have been made available to the author by the Pacific Environmental Group of the US National Marine Fisheries Service. These areas of the western approaches to Great Britain were selected because they have been well covered by ships and virtually complete monthly data are available from 1854 to 1968, updated to 1973 by data supplied by the UK Meteorological Office.

(2) As an index of changes in the strength of flow of the Gulf Stream, Martin[4] has recently presented a time series of data for mean sea level at points along the coast of Florida, for the period 1902–64.

(3) Cohen and Sweetser[5] have provided a time series of freqencies of tropical cyclones in the Atlantic for 1871–1973. The positions and intensities of the semi-permanent centres reflect the conditions for the formation and movement of hurricanes and Namias[6] has shown that a southward
Fig. 1 *a*, 5-yr running mean of average sea level at stations along the coast of Florida, redrawn from Martin[4]. *b*, 7-yr running mean number of Atlantic tropical cyclones, redrawn from Cohen and Sweetser[5]. *c*, Smoothed variations of sea-surface temperature for Marsden square 182B (50–55°N, 15–20°W). *d*, Smoothed variations of sea-surface temperature for Marsden square 145D (45–50°N, 5–10°W). The variables in *c* and *d* were both smoothed by the application of eigenvector filters which, in both instances, were approximately equivalent to 7-yr running means. Inset shows position of Marsden squares 145 and 182.

shift of the Azores high is associated with diminished hurricane activity. It follows that the frequency of tropical cyclones can be used as a guide to the long term changes in the intensity of atmospheric circulation over the North Atlantic.

These three time series are illustrated in Fig. 1, all expressed as smoothed variables (see legend). The general similarities between the long term patterns of change are obvious, showing that low sea-surface temperatures in the North Atlantic are associated with a higher-than-normal flow in the Gulf Stream and a lower-than-normal frequency of tropical cyclones, indicating an above average intensity of the mid-latitude westerlies. Martin illustrated the relationship between Gulf Stream flow and sea-surface temperature in an area off the west coast of Scotland (data from Smed[7]) and he considered that this supported the proposal by Iselin[8] that strong flow in the Gulf Stream leads to a retention of warm water in the North Atlantic Gyre and a reduction in the flow of this water in the North Atlantic Drift, with a consequent drop in temperature. This conflicts with Bjerknes' interpretation that cooling is caused by upwelling induced by increased cyclonic wind-drag:

If the Martin–Iselin interpretation, based on advected changes, is correct, then one would expect the cooling and warming trends, measured at the sea surface, to be more pronounced during the winter and spring in the absence of vertical temperature stratification, while cooling by upwelling should be equally or even more pronounced during periods of summer stratification.

Examination of the time series of sea-surface temperature data for individual months in Marsden squares 182 and 145 indicates that, while a common long-term pattern of change is present in each month of the year, it was clearest in the winter and spring months, whereas during stratification (Schroeder[9]) it tends to be obscured by higher frequency variations, presumably because of local fluctuations in radiation. Thus, these data clearly support the hypothesis that temperature change is produced by advective processes as opposed to upwelling.

It would appear that the time series illustrated in Fig. 1 provides a description, in relative terms, of the major climatic elements of the North Atlantic Ocean covering the past hundred years. It must be stressed that these series contain little or no evidence on which to base predictions; moreover, there are shorter-term phenomena of equal or even greater magnitude which influence both the atmospheric circulation and sea temperatures. Nevertheless, it is of interest to compare the long term history of variations in sea-surface temperature with the more recent changes. Wahl and Bryson[10], on the basis of Rodewald's studies of data from the ocean weather stations, state that "it seems that we have experienced, in the past 29 yr or so, a change in Atlantic Ocean temperatures which amount, in the Gulf Stream vicinity, to about one-sixth of the difference between total glaciation and our present climate"; they also mention two other recent changes with equivalent magnitudes: the northward penetration of the monsoon rains in West Africa and a global increase in average snow and ice cover. The temperature series presented in Fig. 1 suggest that, although there has been a marked drop in temperature in the north-eastern Atlantic, it still has some way to go before attaining values similar to those for the 1920s and there is no evidence from any of the variables that the recent changes are in any way different from those of similar, or even larger, magnitude that have occurred during the past hundred years.

An approximately 10-yr periodicity in sea-surface temperature variations has been reported for several areas of the North Atlantic by Maximov[11] (based on anlyses of data presented by Smed[7] for the period 1900–1960) and also by Southward et al.[12], for a station in the English Channel from the early 1920s. Both reports draw attention to a possible

relationship with the 10–11 yr cycle in the numbers of sunspots.

The sea-surface temperature data for Marsden squares 182 and 145 have been analysed by a filter technique based on the calculation of eigenvectors of the matrix of serial correlations for a specified maximum lag. These analyses showed that the dominant systematic pattern of variation of the residual time series, following the removal of the long term trends contains considerable 10–11-yr periodicity which tends to be in phase with the sunspot cycle, with high temperature anomalies corresponding with sunspot maxima.

The recent work of Parker[13] on pressure distributions in January and July for the period 1750–1958 clearly associates a deepening of the Iceland low in January with the descending phase of the sunspot cycle. This is supported, in general terms, by the data presented by Lawrence[14] of pressure distributions for the month of June for the last eight sunspot cycles (1880–1960). The phase relationships are somewhat confused but the most likely implied association is between a deep Iceland low and positive temperature anomalies. This appears to conflict with the general pattern of intense westerlies and low temperatures. In this case, however, the deepening of the Iceland low is associated with positive pressure anomalies in the area of the Barents Sea and therefore with an increase in southerly anomaly winds over the North Sea and at least some way out over the north-eastern Atlantic. This seems likely to account for the positive relationship between sea-surface temperature and sunspots at the English Channel station and may well apply to areas further out in the Atlantic.

This study is part of the programme of the Institute for Marine Environmental Research, a component of the NERC; it was commissioned in part by the Ministry of Agriculture, Fisheries and Food.

Mantle composition derived from the chemistry of ultramafic lavas

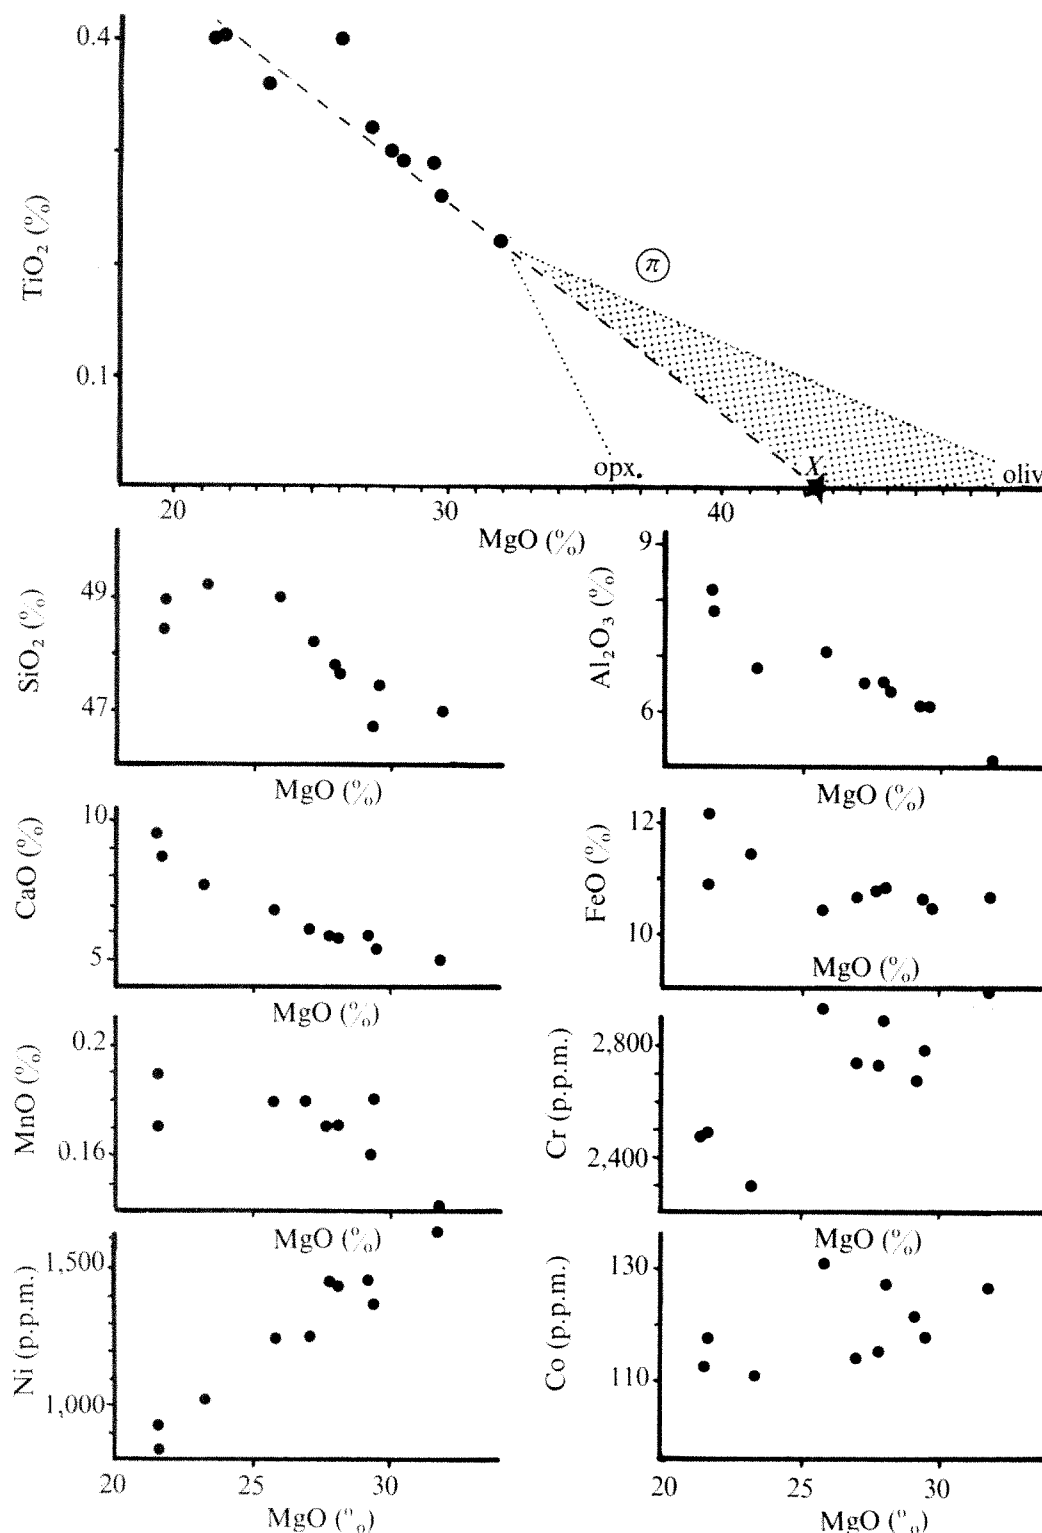
ESTIMATES of the composition of the Earth's mantle have been based on both geochemical and geophysical studies (refs 1–3). As might be expected, there are some discrepancies between the estimates particularly for Na_2O and TiO_2. Such discrepancies in part arise from uncertainties concerning the degrees of melting which many volcanics represent and, possibly, the restricted tectonic settings of the ultramafic nodules studied. High MgO basalts and ultramafic lavas, some of which have been termed komatiites[4] occur among the Archaean volcanic rocks. They represent exceptionally high degrees of melting (up to 50% or more) of peridotite source regions. Potentially such volcanics may be used to make a precise estimate of the composition of their mantle source region. High MgO lavas are well preserved in the Archaean Belingwe greenstone belt of southern Rhodesia, where they form part of a sequence deposited


Fig. 1 Major and trace element compositions of ultramafic lavas rescaled to ignore the water content of the rock. The TiO_2 against MgO graph illustrates the method of estimating mantle composition. Regression lines with MgO as the independent variable give liquid compositions at 22% and 32% MgO (Table 1). X is the composition of the solid residue added to the 22% MgO liquid to give the 32% MgO liquid during partial melting

(assuming that TiO_2 is partitioned completely into the liquid). The solid residuum in equilibrium with the 32% MgO liquid is constrained to lie between X and an olivine composition of $Fo_{93.5}$ (see text). π = Archaean pyrolite. The shaded area shows the range of possible source compositions if the residuum evolves towards olivine.

unconformably on granitic crust[5]. We assume that the occurrence of pillow lavas in this sequence containing both skeletal olivine spinifex ($Fo_{92.5}$ in a rock with 28% MgO, E. G. Nisbet, M. J. Bickle and A. Martin, unpublished) and skeletal olivine microphenocrysts indicates that these particular lavas have a composition close to that of the liquid.

Here we present an analysis of these rocks. Only analyses of pillow lavas and thin (2–12 m) flows are considered since rocks with coarse spinifex zones or thicker ultramafic layers are less likely to represent liquid compositions. Because all of these lavas have undergone low greenschist metamorphism (relict clinopyroxene and olivine are preserved)[5] we include only

*Values for Na₂O, K₂O and P₂O₅ in columns (5) and (6) are approximated using analyses from thicker but less altered ultramafic units containing euhedral olivines (E. G. Nisbet, M. J. Bickle, and A. Martin, unpublished data).

†Olivine:liquid and orthopyroxene:liquid distribution coefficients of 0.01 and 0.002 for Ce and 0.01 and 0.1 for Yb (ref. 10), are used to calculate their concentrations in columns (3) and (4).

those elements which are relatively unaffected by low grade metamorphism. REE patterns are considered not to have been significantly altered during metamorphism if they are smooth (without any marked kinks or unevenness) and parallel in different samples of similar rock types.

The major and trace element composition of ten ultramafic lavas are plotted against their MgO contents in Fig. 1. Like some other Archaean ultramafic lavas, these have low incompatible element contents and CaO–Al₂O₃ ratios around unity. With the exception of Na₂O and K₂O all the variation diagrams show reasonable linear correlations (Fig. 1). The correlations permit an estimate to be made of the bulk composition of the material added to the melt (in a partial melting model) or removed from the melt (crystallisation model) as it progresses from 32 to 22% MgO. It is important to note that this material (henceforth termed X) need never have existed as a real solid. Its MgO content is taken to be that at TiO₂ = 0.0, since only olivine and orthopyroxene are likely to be in equilibrium with such magnesian liquids. The normative composition of X does in fact contain olivine and a significant amount of orthopyroxene. A similar MgO content is obtained for CaO = 0.0. Titanium was chosen as an incompatible element likely to be almost exclusively partitioned into basic melts[4] (minerals from harzburgite nodules have a very low TiO₂ content).

The chemical variation in Fig. 1 suggests that the melts must have evolved leaving a residuum containing both olivine and orthopyroxene. Moreover, the graphs of Cr₂O₃ and Al₂O₃ against MgO indicate that reasonable initial mantle compositions of these phases cannot control these trends. We consider, therefore, that the melts evolved in equilibrium with a solid residuum containing high NiO olivine and high Cr₂O₃, Al₂O₃ orthopyroxene.

Some constraints may be placed on the likely composition of the source by attempting to sum the compositions of the melt and residual phases in their correct proportions.

Two estimates must be made: first, the MgO content of the source, from which the degree of partial melt needed to produce the 32% MgO liquid can be calculated. We arbitrarily chose MgO 41% (based on published analyses of ultramafic nodules), Second, we must estimate the composition of the residuum in equilibrium with the most magnesian liquid observed at the

surface (32% MgO). The Mg–Fe ratio of the residuum is likely to be greater than that of X.

Estimates of the source composition have been made for two cases; an olivine : orthopyroxene residuum in the same ratio as the normative content of X; and a pure olivine residuum (similar to the Fo_{92.8} olivine observed in an ultramafic lava^r). Demonstrably neither of these situations can be correct but the actual source composition probably lay within these limits.

The computed major element contents are remarkably similar to that of garnet lherzolite nodules in kimberlites (Table 1). The total Fe and Al₂O₃ are slightly higher (Fe is dependent on the Mg:Fe ratio assumed for the residuum) and SiO₂ possibly lower than the average of lherzolite xenoliths (Table 1). If a mantle MgO content of 37% were assumed, the SiO₂ content would be higher and the TiO₂ and CaO content lower than pyrolite[3].

The concentration of the incompatible elements (TiO₂, CaO, K₂O, NaO, REE and to a lesser extent Al₂O₃ and MnO) in the source depend only slightly on the concentration of these elements assumed for the residuum (see Table 1). The calculated concentrations of compatible trace elements (NiO, Cr₂O₃) is, in contrast, strongly dependent on the composition assumed for the residuum.

The REE patterns of the komatiites exhibit a depletion in light (relative to heavy) rare earths (Fig. 2). The Ce and Yb contents of the source are reasonably well constrained between 0.51–0.78 and 0.23–0.33 p.p.m. respectively. These estimates are less than the average chondrite value for Ce and between 1 and 1.5 times chondrite for Yb and are significantly lower than previous estimates of REE abundances in the mantle (3–5 times chondrite, see ref. 8). This particular mantle segment was probably less depleted in light REE than the source of some modern mid-ocean ridge tholeiites[9].

Our work shows that a source mantle similar in composition to modern garnet lherzolite nodules in kimberlites could have produced komatiitic liquids. A pyrolitic source, even when extrapolated to similar MgO contents, is enriched in TiO₂ and CaO and depleted in SiO₂ relative to the source of these komatiites. Finally, if the approximately chondritic value of REE abundance in the komatiite source is typical of large portions of the upper mantle, then the degree of total REE enrichment
Fig. 2 Chondrite normalised rare earth distribution patterns from ultramafic lavas (23–30% MgO) Belingwe, Rhodesia. Analysis carried out by the mass spectrometric isotope dilution technique described by Hooker *et al.*[11].

(relative to source) observed in both Archaean tholeiites and mid ocean ridge basalts may be much greater than had previously been imagined[8,12].

Photochemical ozone in the atmosphere of Greater London

ATMOSPHERIC pollution in Greater London is usually associated with high concentrations of smoke and sulphur dioxide, but continual changes in human activity can lead to other types of pollution. One example is the reported occurrence of elevated ozone concentrations indicative of photochemical activity[1]. I present details of the spatial and temporal variation of ozone concentrations experienced in Greater London during the summer of 1975. The data are presented, in part, with reference to the Greater London Council (GLC) guideline concentration for ozone of 0.08 p.p.m. (1-h average)[2,3]. Observations indicate that photochemical ozone in and around London is likely to have a dual origin, namely, the European continent (see ref. 4), and photochemical reactions involving locally emitted precursor pollutants.

During the period May–September 1975 the Scientific Branch of the GLC monitored ozone at three sites in Greater London, two of which were located in suburban areas at Teddington and Hainault, with the third at County Hall in the centre. Teddington lies 18 km south-west and Hainault 19 km north-east of the centre. The suburban sites were equipped with ozone detectors operating on the principle of ultraviolet absorption. At County Hall a chemiluminescent ozone analyser was used. All three sites were as far removed as possible from local sources of pollution, especially heavily-trafficked roads. The ozone instruments were cross checked and calibrated at the beginning and end of the season against a constant ozone source, itself standardised against a neutral-buffered KI solution[5]. Further cross checks were made between the two types of instrument in polluted atmospheres. Ozone concentrations were recorded at 30-s intervals on magnetic tape suitable for computer processing.

Figure 1 shows maximum hourly mean concentrations of ozone at each site during the monitoring period. Occurrences of elevated ozone concentrations are superimposed on a background concentration of 0.02–0.04 p.p.m. The background seems to represent the natural ozone content of the troposphere in this region, and is consistent with measurements reported for other parts of Britain[4]. With reference to the GLC guideline concentration the first conclusions that can be drawn are:

Fig. 1 Daily maximum hourly means of ozone: *a*, Hainault; *b*, County Hall; *c*, Teddington.

April 30   May 30   June 29   July 29   August 28   September 27
1975
● During May to September 1975 ozone concentrations exceeded the GLC guideline on approximately 15% of days.
● The guideline was exceeded for approximately 100 h at Hainault, 79 h at County Hall and 129 h at Teddington during this period.
● The highest hourly mean concentration recorded at these sites was 0.15 p.p.m. at County Hall, on June 26, 1975.

A study of the meteorological records of the London Weather Centre shows that days with high afternoon ozone concentrations generally coincide with both low early morning wind speeds, usually of less than 3 m s⁻¹, and high solar radiation[*]. An association of oxidant incidents with inversion conditions as measured at Cardington, Bedford-shire, has also been found; it is statistically significant at the 0.1% level. During the summer of 1975 the GLC guide-line was exceeded at one or more of the Greater London sites on 56% of occasions on which the 0500 Balthum ascent from Cardington registered an inversion strength of 4 °C or more. Conversely, for weaker or nonexistent inversions, the guideline was exceeded on only 4% of occa-sions. Figure 2 shows such information for the period June 25–27, 1975. The key factor in the ozone incident of June 26 is thought to be the development of a strong inversion during the previous night, which encouraged the buildup of locally generated oxidant precursor pollutants, oxides of nitrogen and hydrocarbons. These subsequently became in-volved in photochemical reactions during the sunlight hours of June 26. The sequence was not repeated the following day, when overnight cloud cover inhibited inversion forma-tion.

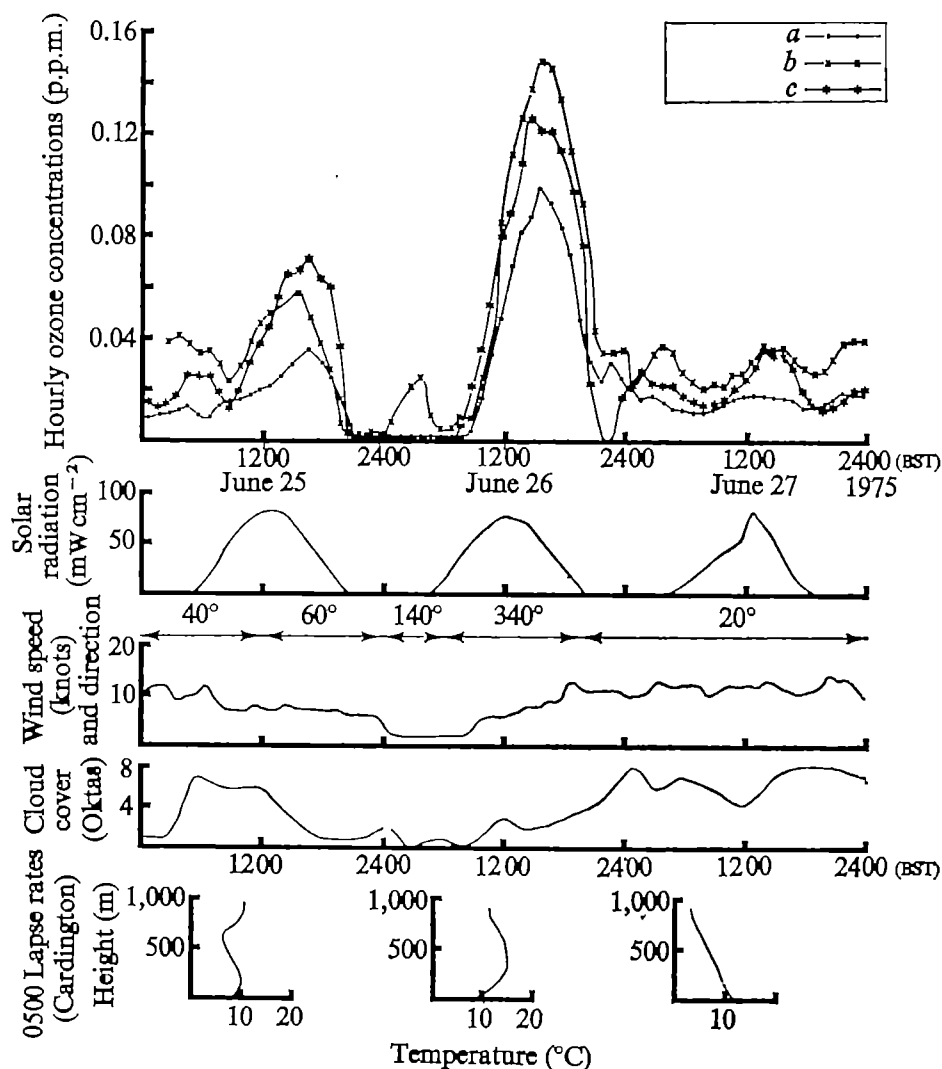
Isolated occurrences of high ozone concentrations, as on June 26 were, however, uncommon. Generally, days with high ozone concentrations tend not to occur singly, but over periods of several days or more[*], and Greater London was no exception during 1975, with the main oxidant incidents

Table 1 Comparison of wind direction (1100–1500) and ozone concentrations at Teddington and Hainault

Date (1976)	Maximum hourly mean	Ozone concentration (p.p.m)	Wind direction (degrees)
	Teddington	Hainault	
June 8	0.122	0.100	060
June 10	0.088	0.065	020
June 13	0.073	0.087	290
July 27	0.104	0.054	120
July 31	0.087	0.072	080
August 1	0.081	0.056	060
August 3	0.116	0.084	120
August 13	0.090	0.103	190

occurring during June 7–12 and July 27–August 14. During the latter period the guideline was exceeded on 14 of the 19 days.

A study of the appropriate Daily Weather Reports shows that on all days with high oxidant levels the synoptic con-ditions were dominated by slow moving anticyclonic cells

Fig. 2 Ozone and meteorological data for the period June 25–27, 1975: a, Hainault; b, County Hall; c, Teddington.


and/or weak synoptic pressure gradients. Anticyclonic conditions are generally characterised by light winds or calm conditions with clear skies. The latter lead to nocturnal inversion, which in turn encourages the buildup of precursor pollutants throughout the whole anticyclonic cell, and the consequent production of oxidants over large areas at any one time. Because the anticyclones are slow moving the conditions tend to persist for days at a time. It is also apparent that on most occasions these cells were centred on the North Sea, North Germany, or Scandinavia. Thus, southern Britain, including the Greater London area, would have been experiencing a light and predominantly easterly air stream of continental origin. This accords with the observations of Cox *et al.*[4], which indicate that photochemical ozone and its precursors may be transported into Britain from continental Europe. In fact, examination of air mass trajectories for 1975 by using the geostrophic wind, as calculated from the Daily Weather Report, shows that most air masses over Greater London on high oxidant days were of continental origin[6].

But a close inspection of the relative values of the maximum hourly means at the Teddington and Hainault sites on high oxidant days on which there was a significant difference in concentration between the two locations shows that the higher concentration is manifest at the site for which the incoming air mass had had the longest trajectory over Greater London (Table 1). In addition, on days characterised by exceptionally long periods with low wind speeds, such as June 26, the highest measured concentration in London, and indeed in the whole of Britain (H.N.M. Stewart, personal communication), occurred in the city centre.

The most likely explanation for these phenomena is that emissions of precursor pollutants from Greater London are reacting photochemically to produce oxidants. The locally generated precursors drift downwind during the late morning and early afternoon and produce higher ozone concentrations on the downwind side, and possibly higher concentrations still beyond the GLC boundary. On particularly calm days the precursors do not drift as far and maximum ozone concentrations tend to arise close to the maximum density of emissions, which is probably in central London. This ties in with the earlier mentioned observation that the GLC guideline was exceeded more in west than in east London, because local winds have tended to be from the eastern sector on high oxidant days.

The picture which emerges is of two sources of oxidants contributing significantly to high ozone concentrations in the atmosphere of Greater London. First, during anticyclonic weather in northern Europe precursor pollutants collect over large areas in what virtually amounts to an outdoor smog chamber. Widespread elevated ozone concentrations are thus formed more or less simultaneously. Ozone, which is rapidly destroyed at the Earth's surface, is then able to persist for several days because low level nocturnal inversions, which form frequently under anticyclonic conditions, inhibit downwind mixing. This allows its transportation over distances of perhaps 1,000 km or more[4], with a possible influx to Greater London. Second, the same synoptic weather conditions favour the simultaneous buildup of locally generated precursor pollutants, and the subsequent formation of oxidants in London's atmosphere.

With forecasts that road traffic will increase significantly in the next decade, continued vigilance is necessary so as to detect, at an early stage, any deterioration in the situation. Although it is apparent that corrective action, should it be required, must be taken in the context of Europe as a whole, the problem of local generation of oxidants warrants individual study as the optimum abatement strategy may vary from one region to another.

Ozone levels in central London

MEASUREMENTS of ozone and some primary pollutants, including oxides of nitrogen and total hydrocarbons, have been in progress at the Central London background site of this laboratory since July 1972. A preliminary note[1] discussed the early results from this site; here we present a statistical analysis of the relationship between ozone levels in Central London and some meteorological parameters measured at the London Weather Centre, ~0.4 km from the sampling site. The data were collected during the periods July–September 1972 and April–September in both 1973 and 1974.

The sampling point at the site, which is located at Endell Street, Holborn, London, is ~10 m above ground, well removed from traffic or any particular pollutant source and is not unrepresentative of the background air in Central London.

An analysis of the time of occurrence of the ozone maximum hourly mean concentration for all the days considered is summarised in Fig. 1. This conforms to the general pattern found in other studies[1,2] with a small percentage of maxima occurring in the earlier hours of the day, arising from the diffusion of stratospheric ozone and the majority of maxima, from photochemical activity, occurring between 1500 and 1600 LT. It is interesting to note that relatively high (>10.9 parts per 10[8]) levels were observed late in the day (1900–2100 LT) on some occasions, a fact which has been taken by Steinberger and Balmor[3] to be indicative of non-local production of ozone.

Fig. 1 Time of occurrence of the maximum hourly mean ozone concentration at Endell St, London for the summer periods 1972–1974.
Table 1 Analysis of the dependence of elevated ozone levels on wind direction

	Wind direction							
	N*	NE	E	SE	S	SW	W	NW
No. of days in given direction	51	67	51	21	40	80	72	38
% of total	12	16	12	5	10	19	17	9
No. of days with $[O_3] \geqslant 8.0$ p.p.10^8 in given direction	4	13	11	5	9	6	6	3
No. of days with $[O_3] \geqslant 8.0$ p.p.10^8 as % of total in given direction (f)	8	19	22	24	23	8	8	8

*Any direction from 337.5°–22.5° is taken as N, 22.5°–67.5° as NE and so on.

An attempt was made to correlate the daily ozone maximum hourly mean concentration with average values for the whole day and the period 0600–0900 h for the primary pollutants NO, NO$_x$ and total hydrocarbons. No significant relationship was found.

A preliminary bivariate analysis of the ozone levels and selected meteorological parameters indicated that the most important factors were maximum daily temperature, relative humidity and daily insolation. A stepwise multiple regression analysis was then performed using the logarithms of these

Fig. 2 Plot of values of ozone concentrations calculated from equation (2) against observed values.

parameters as independent variables with the logarithm of the ozone concentration as dependent variable. The number of days for which valid data were available was 453. The regression equation obtained was

$$[O_3] = 0.60 \, T^{0.64} \, I^{0.31} \, H^{-0.43} \tag{1}$$

where T is the maximum daily temperature (°C), I is the total daily insolation (mWh cm^{-2}) and H is the relative humidity (%). The multiple correlation coefficient obtained was 0.623. Adding wind speed to the regression gave no significant improvement. An analysis of the residuals yielded a Durbin–Watson statistic of 1.145 indicating autocorrelation in the ozone levels. On including the logarithm of the previous day's ozone concentration in the set of independent variables the multiple

correlation coefficient improved to 0.712. The regression equation obtained was, in an obvious notation

$$[O_3]_t = 0.68 \, [O_3]_{t-1}^{0.38} \, T_t^{0.37} \, I_t^{0.28} \, H_t^{-0.36} \tag{2}$$

The partial correlation coefficients of the independent variables are, in the order in which they appear in equation (2), 0.44, 0.19, 0.24 and −0.17, (all significant at the 1% level).

The standard error in reproducing observed ozone levels using this model is ±2.1 parts per 10^8 (see Fig. 2) so that in predicting elevated levels, that is, those $\geqslant 8.0$ parts per 10^8 this implies a confidence limit of ±~26%. We therefore present equation (2) as a model for ozone concentrations at the Central London background site.

We have attempted to analyse the effect of wind direction as measured at the London Weather Centre on the ozone levels. The results of this analysis are shown in Table 1 and a plot of the percentage of days with wind from a given direction when levels $\geqslant 8.0$ parts per 10^8 occurred is shown in Fig. 3. It is clear from this histogram that the majority of elevated zone levels occur on days when the wind is from a direction ranging from north-east through to south. These conditions prevail, in general, when an anticyclone is present over the North Sea or north-western Europe when the air flow is from the Continent.

It should be borne in mind that the wind direction as measured at a particular location, in our case the London Weather Centre,

Fig. 3 Plot of number of days with ozone concentration $\geqslant 8.0$ parts per 10^8 expressed as a percentage (f) of the total number of days with wind in a given direction.
is not necessarily a precise indicator of the actual trajectory of the air mass which might be responsible for the transport of pollutants. Consequently further refinement of the model to include wind direction in a more quantitative manner, by stratifying the data in wind sectors for example, was not felt to be justified.

From a consideration of the wind direction analysis and the times of occurrence of the elevated ozone levels it is likely that a significant proportion of the ozone measured at Endell Street is transported there, but further investigation would be necessary to determine the source areas. One possibility is that the continental air mass contains precursor pollutants and produces ozone as it flows over north-western Europe giving rise to elevated levels even at rural sites well away from sources of pollution. Elevated ozone levels measured at Adrigole on the West Coast of Ireland lend support to this idea and Cox *et al.*[2] have discussed this point at length, concluding that ozone and precursors could be transported over distances up to 100–1,000 km.

Gravity counteracts light-induced inhibition of root growth

THE view that roots are generally indifferent to light has recently been revised in the face of evidence that light can be inhibitory to the growth of some roots[1-10]. The discovery[6,11] that light affects the production of an inhibitor prompted the suggestion[8] that sensitivity to light in roots is related to the system controlling geotropic response, which is also dependent on the presence of an inhibitor[12,13]. Since the onset of geotropic responsiveness in some roots is dependent on exposure to light[14-16], the suggestion seems well founded and attempts are being made to clarify the extent to which the mechanisms, triggered when light or gravity affects the root, are interrelated. The investigation described here was prompted by the report[9] that roots of cress seedlings grown in Petri dishes in the light were stunted in comparison with similar seedlings in the dark. If light promotes geosensitivity, distorted growth could develop in a situation where the root is unable to realign itself, as for example when it is restricted to the horizontal plane. A study was therefore made of the influence of the plane of growth on the light-induced inhibition of root

elongation in cress seedlings, from which it seems that although light does not enhance geosensitivity, light-induced inhibition is manifest only in horizontally grown roots and can be prevented by subjecting the roots to a force field.

Seeds of *Lepidium sativum* L. cv. Curled were moistened with 0.1 mM $CaCl_2$, pH 6.5, and left for 20 h at room temperature in normal lighting conditions. Seeds which were at a uniform stage of germination—the testa having split open but before the emergence of the radicle—were then placed with the radicles pointing downwards on a 11.5-cm circle of Whatman No. 1 filter paper in a glass Petri dish (115×18 mm) containing 6 ml of 0.1 mM $CaCl_2$. For dark treatments Petri dishes were either sprayed externally with black paint or wrapped in aluminium foil. The dishes were placed on a bench continuously illuminated by a bank of fluorescent tubes giving an incident light intensity of about 20 W m^{-2} at the level of the Petri dishes. The dishes were placed horizontally, parallel to the light source, or at angles of 10°, 45° and near vertical (85° to 90°). For the angled dishes side illumination was also provided but growth showed no dependence on the direction of the light source. Cress roots are not negatively phototropic. Root lengths were measured at 24-h intervals after treatment began, that is approximately 44, 68 and 92 h after the seed was wetted.

Table 1 shows a comparison of root growth of seedlings in the light and in the dark as affected by the plane of growth. The reported inhibition[5] of root growth in the light was evident in horizontal roots at 44 h, and this inhibition continued into the following 2 d, although with time the growth rate of horizontal roots in the light increased. With vertically orientated seedlings in the light there was no inhibition of root growth relative to horizontal roots in the dark. The ability of light-exposed roots to overcome light inhibition is clearly a function of the plane of growth, an angle of 10° having a discernible effect. At 45° the growth rate was not far short of that obtained on the vertical. Since the component of the Earth's gravitational field in the plane of growth is determined by the sine of the angle subtended with the horizontal, an angle of 45° would produce a force of approximately 0.7*g* and therefore it would be expected that this slope would give a growth rate approaching that of the vertical. Roots growing in the dark also showed a positive response to being aligned with the Earth's gravitational field but the percentage increase was much less than in the light.

These results indicate that when the force of gravity acts on a seedling growing in a vertical plane the light-induced retardation of growth observed in the horizontal plane is largely eliminated. Two further questions are thus raised. First, is horizontal root growth inhibited in the light in the absence of gravity and second, is horizontal root growth inhibited in the light when the root is subjected to a force field applied on the horizontal plane? An answer to the first question was sought by placing imbibed seed on moist filter paper on the base of a crystallising dish which was illuminated and, with the base vertical, was then rotated

Table 1 Effect of the plane of growth on the length (mm) of cress seedling roots in the light and dark

Treatment	Time of measurement (h)	Angle subtended with the horizontal			
		0°	10°	45°	85°
Light	44	6.1 ± 0.28	10.5 ± 0.39	12.8 ± 0.40	16.1 ± 0.49
	68	15.7 ± 0.66	35.3 ± 1.73	43.2 ± 0.90	50.5 ± 1.06
	92	30.5 ± 0.91	69.4 ± 2.82	76.8 ± 1.62	90.7 ± 1.86
Dark	44	14.7 ± 0.55	17.1 ± 0.63	20.3 ± 0.51	21.3 ± 0.46
	68	39.5 ± 1.42	51.5 ± 1.31	56.0 ± 1.35	60.2 ± 0.71
	92	65.6 ± 2.44	79.7 ± 2.24	80.3 ± 1.64	88.6 ± 1.99

Twenty seeds were placed in Petri dishes as described in the text and the growth of the roots was measured over 4 d at 25 °C. The Petri dishes were clamped at the angles shown and care taken to ensure uniform illumination at an intensity of approximately 20 W m^{-2}. Each treatment was in duplicate and the values shown are the mean ± s.e. of 40 seedlings.

round a horizontal axis in the manner of a clinostat. The second question was answered by placing a circle of imbibed seed so as to form a hub on filter paper in a Petri dish which was then illuminated and spun at 150–200 r.p.m. (1–2*g*) in a horizontal plane. Table 2 shows that where the effect of gravity was neutralised, and with the root free from the restraints imposed by a horizontal barrier, a light-induced inhibition of root growth was still evident. But this inhibition could be overcome on the horizontal plane by applying a centrifugal force comparable with that of gravity.

The question posed above concerning the geosensitivity of cress roots in light and dark was answered by making a 90° rotation of Petri dishes containing seedlings growing vertically in the light and in the dark. In both cases the roots reorientated themselves with the field of gravity irrespective of whether they were, or had been, in the light or in the dark. The light-induced root inhibition exhibited by horizontally grown seedlings is not therefore attributable to an enhanced geosensitivity not possessed by the seedlings grown in the dark.

Table 2 Effect of force field on the growth of cress seedling roots

Treatment	Radicle length (mm)
Light horizontal	6.7±0.38
As above with centrifugal force	17.8±0.71
Gravity neutralised	
dark seedlings	14.0±0.71
light seedlings	6.2±0.20

Seeds were imbibed for 20 h and then 20 seeds were placed in each of the dishes as described in the text and subjected to treatment for the following 24 h at 25 °C. The centrifugal force applied on the horizontal plane was between 1 and 2*g*. Gravity was neutralised by rotating the vertically-orientated dishes round a horizontal axis at 5 r.p.h. Values shown are mean ± s.e. for each treatment.

It is evident that in cress roots, growth is promoted by the longitudinal force exerted by gravity, one effect of which is to counteract the inhibitory effect of light. Not only root growth is promoted. As the steepness of the plane of growth increases so does the growth of the seedling, the cotyledonous leaves emerging and greening more rapidly than when horizontal. This points to an overall effect of gravity on the rate of hormone production or transport or both.

The cress root is a classic object for the study of amyloplasts, the gravity-sensing organelles present in the root cap[17,18]. Audus[19] has suggested, on the basis of work by Sievers and Volkmann[20], that mechanical pressure exerted by the amyloplasts on the membranes of the endoplasmic reticulum, or some other non-migratory cellular component, could result in the production of a regulatory compound in the root cap. This is envisaged in terms of a differential flow of inhibitor leading to a curvature of the root, but it seems reasonable that a preferred orientation of amyloplasts should also give a minimum flow of inhibitor or an optimum flow of regulators.

It has been suggested that root growth is controlled by two hormonal systems[19,21]. Light is known to promote the acropetal movement of indolyl acetic acid in *Zea* roots[15] and it has been reported that the gravity-promoted basipetal movement of a growth inhibitor in *Zea* is dependent on light[8,22]. The results reported here show that gravity can interact with light antagonistically in the overall control of root growth. Identical results have also been obtained with seedlings of *Lactuca sativa* and *Brassica hirta* in both of which the roots, in contrast to those of cress, are strongly negatively phototropic, and in both of which a pronounced light-inhibition on the horizontal plane is relieved on the vertical plane. This phenomenon might prove useful in the investigation of the changes in hormone production and

transport brought about by amyloplasts sedimenting under the influence of gravity.

Heterochromatin polymorphism and colour pattern in the tiger swallowtail butterfly *Papilio glaucus* L.

THE difference between the black mimetic and yellow non-mimetic female forms of the tiger swallowtail butterfly, *Papilio glaucus* L., is probably controlled by a locus on the Y (W) chromosome (cytoplasmic inheritance is less likely). Since the female is the heterogametic sex in the Lepidoptera black females should produce only black daughters and yellow females only yellow ones, and here we report cytological differences between the two.

It is known that occasional yellow females arise from black ones and vice versa, and in our broods four black females gave rise to a minority of yellow daughters, and two yellow ones to a minority of black[1]. Haldane[2] suggested that these exceptional broods might be explained by occasional crossing over between the X and the Y chromosome, plus a position effect, such that black pigment is only laid down by the appropriate allelomorph when this is on the Y chromosome. Furthermore, he thought a position effect to be particularly likely because of the tendency for inert chromatin to be present on the Y chromosome.

The difficulty with Haldane's explanation of the exceptional *glaucus* broods is the fact that crossing over is believed not to occur in female Lepidoptera[3-5]. Our recent cytological evidence however, lends striking support to Haldane's view that heterochromatin is involved in the expression of the black phenotype.

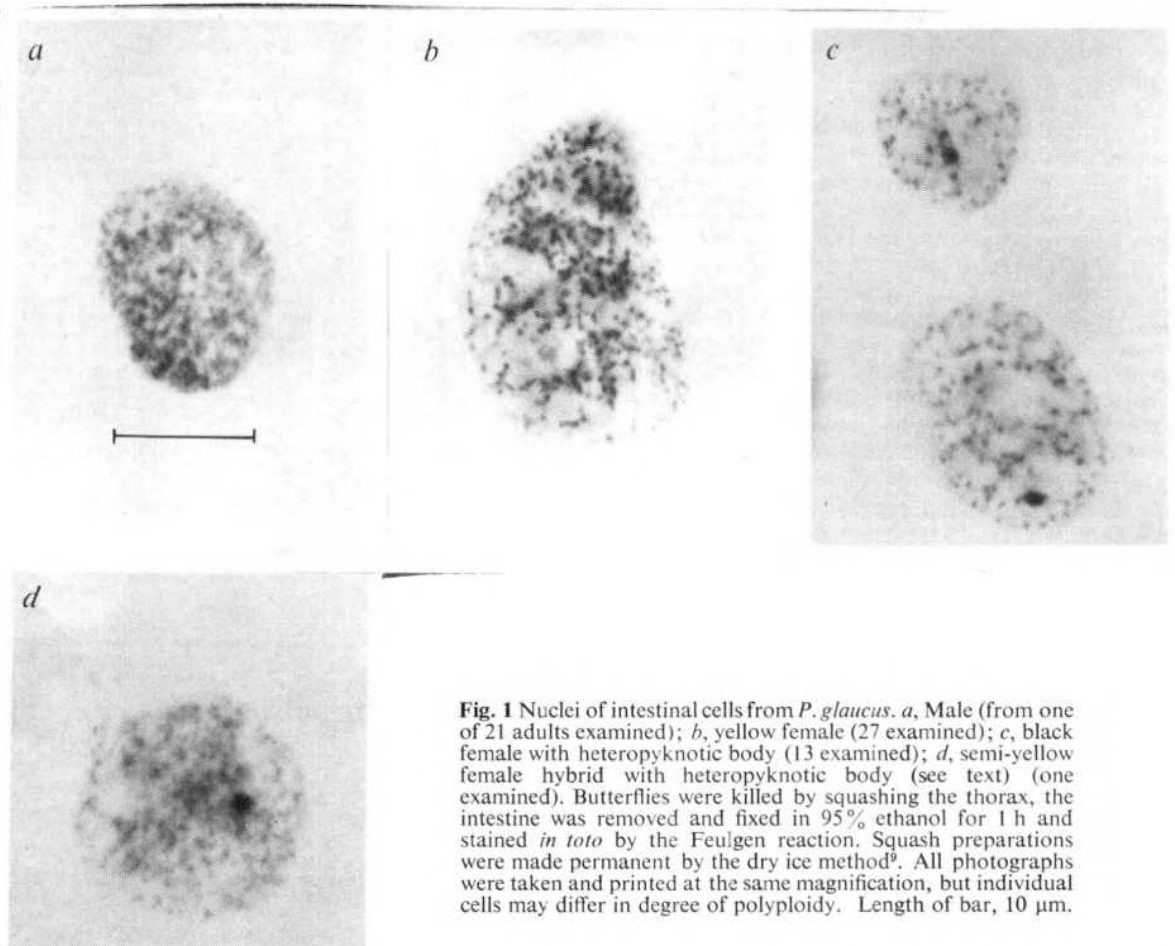
We have examined some of our *P. glaucus* males and black and yellow females and found that the black females possess and the yellow ones lack the heteropyknotic sex chromatin body (Fig. 1) described by Smith[6] and later shown to be the heterochromatin on the Y (W) chromosome[7]. The yellow butterflies tested were the male and female descendants of two wild yellow females from New Jersey, and the female descendants of a yellow female from West Virginia. All were Smith negative. Among the descendants of three wild black females from West Virginia and one from Chicago, the males were again negative, but in contrast all the females were Smith positive. Thus the black females and the (yellow) males are characteristic of the cytological picture of most Lepidoptera, whereas the yellow females are behaving like those of a minority of species where no heterochromatic body is found in either sex[8]. In the only other minority category known to occur, there is a body in both sexes, and in at least one species (*Papilio machaon* L.) the male is polymorphic for the presence or absence of the body (our work with W. Traut, in preparation).


Fig. 1 Nuclei of intestinal cells from *P. glaucus*. *a*, Male (from one of 21 adults examined); *b*, yellow female (27 examined); *c*, black female with heteropyknotic body (13 examined); *d*, semi-yellow female hybrid with heteropyknotic body (see text) (one examined). Butterflies were killed by squashing the thorax, the intestine was removed and fixed in 95% ethanol for 1 h and stained *in toto* by the Feulgen reaction. Squash preparations were made permanent by the dry ice method[9]. All photographs were taken and printed at the same magnification, but individual cells may differ in degree of polyploidy. Length of bar, 10 μm.

P. glaucus is widely distributed in North America, and we have not examined sufficient females from different localities to be certain that the 1:1 correspondence between female colour and heteropyknotic state in our study is not due to geographical heterogeneity in the cytological picture. The correspondence, however, suggests that in the exceptional segregating broods where the mother is black, the Y chromosome bearing the locus for the black gene is occasionally lost from the eggs of black females, who would then produce yellow daughters. It is more difficult to see how the body could be gained as it would have to come from a non-homologous chromosome. Possibly relevant is the fact that, as we noted[1], all our exceptional broods stemmed from females which may well have been related and have a chromosome abnormality resulting in loss or gain of heterochromatin by the Y.

There is another aspect of the Smith body in our work on *P. glaucus*. To be certain that the exceptional females were not mistakes due to the interchange of larvae between broods, we hybridised black *P. glaucus* females with the yellow monomorphic allopatric species *P. rutulus* Lucas because the hybrid larvae are recognisable. This cross produced no adult females, so we backcrossed the male progeny to black *P. glaucus*. We obtained some broods which segregated for black and yellow females and others in which a proportion of the black females had various degrees of yellow scaling, but none was fully yellow. The segregation (25 pure black in 41 females) suggests a 1:1 ratio, a situation quite different from that in pure *P. glaucus*. Since we began to use the Smith technique we have found that the only hybrid semi-yellow female (dissected and found to be a normal female) that has been tested possesses the heterochromatic body characteristic of black *P. glaucus* (Fig. 1*d*): two of her all-black sibs also had the body. In the progeny of the backcross to yellow the body was absent.

The segregation of yellow and black in the *P. rutulus* hybrids seems therefore to be due to an allelomorph suppressing black, introduced from *P. rutulus*. This is supported by the fact that the

segregation in the backcross occurs in the progeny of females that were pure black *P. glaucus*. It seems therefore that the black form can be altered in two ways, either by bringing in a modifier not on the Y chromosome from the allied *P. rutulus*, or by a change on the Y chromosome associated with the absence of the heteropyknotic body within *P. glaucus*.

It is important to know the state of the heteropyknotic body in the three allopatric species *P. rutulus*, *P. multicaudatus* Kirby and *P. eurymedon* Lucas, since the ancestral cytological state is likely to have been that found in black *P. glaucus* today (the majority situation) and it is interesting from the evolutionary point of view to know whether the heteropyknotic body has been lost and regained, or merely lost in yellow *P. glaucus*.

Since our manuscript was submitted adult females have been obtained from black *P. glaucus* females and *P. rutulus* Lucas. On July 8, 1976 two perfect females were made to eclose by Dr Axel Willig of the University of Ulm, using α-ecdysterone. The insects resemble the yellower intermediate backcross females and have a Smith body.

Diet influences attractiveness of urine in guinea pigs

INTRASPECIES chemical communication with urine-borne substances is widespread in mammals. Numerous reports have indicated that the nature of the messages transmitted in urine depends on such factors as the hormonal state, the age, the individual identity and the level of stress of the sender[1,2]. I report here that information transmitted in urinary signals also depends on the diet of the sender. These findings have important implications for the study of animal chemical communication systems[3].

Chemical signals have an important role in social interactions of the guinea pig. In seminatural settings, subordinate females spray males and other females with urine whereas males often spray females during courtship. Scent-marking behaviour in this species results in placing urine as well as glandular secretions throughout the environment[4,5]. In laboratory studies, males spend more time investigating female conspecific urine than male conspecific urine, urine from other species, or water[6,7].

To examine whether the diet of an animal influences the information contained in the urine, 12 individually housed, sexually mature, socially experienced male guinea pigs were given a series of preferences tests (single-sample tests and two-choice tests) between urine collected from donors on different diets. The tester was always unaware of the source of the urine being tested. A finding that urine from one source is preferred to urine from a second source is evidence that the two samples possess different information. The urine to be tested was collected from adult, intact sexually non-receptive female and adult male guinea pig donors using metabolism funnels. Different donors were used in each experiment. All urine was frozen until shortly before use. In the first experiment, urine from four male and four female donors was used. Twenty-two hours before the first urine collection two female donors and two male donors, randomly selected, were provided with crushed (Purina) rat food (RF) and water. The other donors remained on (Wayne) guinea pig food (GPF). All donors' food was removed and urine was collected during the next 2 h. Urine from donors eating the same food (GPF or RF) and from donors of the same sex (♀♀ or ♂♂) was pooled and two series of single sample tests[6,7], separated by 2-d rest, were conducted. Each male was tested with ♀♀ GPF urine, ♂♂ GPF urine, ♀♀ RF urine, ♂♂ RF urine and water. The weights of the donors either increased slightly or remained constant during the 22 h on experimental diets.

The results (Fig. 1) show that females on a RF diet produce urine which is less attractive than that of females eating GPF. This occurred even though the donors were fed the new diet for only 22 h preceding urine collection. Even though the attractiveness of ♀♀

RF urine is, however, depressed, this urine is still investigated more than ♂♂ GPF urine, confirming the previously documented preference for female urine over male urine by male recipients[6,7].

To examine the generality of this finding, urine from female and male guinea pigs fed a semisynthetic diet (Reed-Briggs) was compared with urine from the same animals fed GPF using a simultaneous two-choice method[6,7]. The urine collected when the donors were on a semisynthetic food was less attractive than urine collected when they were on GPF (Table 1, experiments 1 and 2), in agreement with the RF results. When the donors were force fed a standard amount (approximately 16 g over 2 d) of either GPF or semisynthetic diet, the results were similar: GPF urine was
Fig. 1 Results of single-sample preference tests. The heights of the bars represent the mean (± s.e.m.) time (s) that the male guinea pigs have their nose within approximately 1 cm of the urine from four sources and water, each presented singly. The four sources are: ♀♀ GPF, urine that was collected from females eating guinea pig food during the 22 h preceding collection; ♀♀ RF, urine collected from females eating rat food over the same period; ♂♂ GPF, urine collected from males eating guinea pig food, ♂♂ RF, urine collected from males eating rat food; water, charcoal filtered and deionised water. For each substance, each animal had a total of two 2-min periods to investigate a sample (0.2 ml) which was placed in the centre of a clean glass plate (7.5 × 15.0 cm). Each sample was tested individually in the subjects' home cage, one sample each day. The order of presentation was randomised. Overall, there was a significant difference among the samples (represented measures ANOVA, $F[4,44] = 21.98$, $P < 0.001$). Those bars not connected by a horizontal line are significantly different from each other ($P \leq 0.05$, Newman–Keuls test).

Table 1 Mean time (s) investigating each of the two guinea pig urine samples in five preference experiments.

Experiment	Donors' Chow	Time (s)		Choice Donors' Chow	Time (s)	P
1*	Guinea Pig	107.0 ± 18.7	*v*	Semisynthetic	44.1 ± 7.2	<0.01
2*	Guinea Pig	92.2 ± 14.1	*v*	Semisynthetic	36.3 ± 7.1	<0.01
3	Guinea Pig	95.0 ± 23.6	*v*	Semisynthetic	37.4 ± 8.7	<0.01
4	Guinea Pig	108.3 ± 21.2	*v*	Rat	50.8 ± 10.1	<0.01
5a	Guinea Pig	36.9 ± 4.7	*v*	Guinea Pig	30.8 ± 6.9	NS
b	Guinea Pig	57.2 ± 9.5	*v*	Rat	19.2 ± 4.8	<0.01
c	Guinea pig	33.2 ± 8.4	*v*	Guinea pig	33.4 ± 7.6	NS

Each experiment except 5 represents two 4-min choice tests with 12 or 13 subjects where the two samples to be compared were presented simultaneously to a subject; in experiment 5, only one 4-min choice was conducted for each of the three tests. For all experiments the donors were four females except for choice 2, where four males served as donors. Probabilities based on two-tailed *t* tests for related measures. See text for further explanation.
*In choices 1 and 2, urine from donors fed GPF was diluted in the appropriate amount with deionised water before testing, since animals on semisynthetic diet drank more water and produced larger volumes of urine.
NS, not significant.

preferred to urine from donors force fed semisynthetic food (Table 1, experiment 3). One possible explanation for the pattern of results is that abrupt short term alteration of the diet stimulates physiological changes that result in the production and urinary excretion of some substance that the male guinea pig subject finds noxious. To examine this question, two female guinea pigs were raised from birth on crushed RF and water fortified with vitamin C. When the animals were well past sexual maturity, urine was collected and compared with urine from littermates reared on GPF from birth. A different group of 13 males was used as subjects in this test. As before, GPF urine was greatly preferred over RF urine (Table 1, experiment 4).

Different groups of animals served as donors for each experiment described above reducing the possibility that the differences observed could be accounted for by inherent differential attractiveness of urine from different animals. To eliminate completely this possibility, however, a final experiment was conducted. From four previously unused female donors of approximately equal age and weight, two were randomly selected to be on RF and the other two were to remain on GPF. Three pairs of urine samples were collected. Immediately before placing the donor pair on RF, urine was collected for 3 h from both pairs (*a*). Immediately after the one pair had eaten RF for 21 h, urine was similarly collected from both pairs (*b*). Finally, GPF was available to both pairs of donors then for the next 21 h after which urine was collected a third time (*c*). The amount of RF consumed during the 21 h (25 and 28 g for the two donors) was similar to the amount of GPF eaten in the same period by the two control donors (26 and 27 g); similarly, body weight remained constant. All females were sexually unreceptive during the 3-d period. In several previous studies we have failed to find any change in the attractiveness of female guinea pig urine as a function of the stage of oestrus. When the three pairs of urine samples were tested using the simultaneous two-choice procedure, it was found that urine from both pairs of donors which was collected before the diet was changed (experiment 5*a*) and urine which was collected after both pairs of donors had been returned to GPF for 21 h (experiment 5*c*) was equally attractive. Urine collected from donors immediately after one pair had been on RF for 21 h was, however, significantly less attractive than urine from donors on GPF (experiment 5*b*).

Leon[8] has demonstrated that the food eaten by a mother rat influences the odours emanating from her caecal contents. His data further suggest that the pups were attracted to odours possessed by their mothers as a result of learning. Analogous hypotheses have been suggested by Hendry *et al.* for some insect pheromone systems[3]. In my experiments, the male guinea pig subjects experienced throughout their lives urine only from animals who had eaten guinea pig food. It is possible, therefore, that the preference shown for urine of guinea pigs fed GPF compared with urine of guinea pigs fed RF or synthetic food is the result of some aspect of previous experience with either guinea pig food or with urine from animals eating such food.

These data indicate that, in nature, male guinea pigs could discriminate among conspecific animals on the basis of previous dietary history. Although it is not surprising that dietary changes provide detectable differences in urinary chemical signals, the differential attractiveness of urine from animals on different diets shows that these differences have a communicative function. It is possible that information on the availability of a new food could be transmitted through urinary chemical signals. The importance of carefully controlling the diet in behavioural and biochemical studies of mammalian chemical communication is evident. Further, these data illustrate the complex nature of the information conveyed in guinea pig urine. In previous chemical studies, it has been found that separation of urine by a variety of procedures resulted in several fractions of widely different chemical character and molecular weight being responsible for its attractive nature of conspecific males[9]. It has been suggested[2] that a pattern of chemical substances may thus be involved in the urinary communication system of Cavia as well as in similar systems in other mammals. The data presented here further support these hypotheses.

Differentiation induced by cyclic AMP in undifferentiated cells of early chick embryo *in vitro*

THE undifferentiated cells of the chick embryo in the post-nodal piece (PNP), obtained by a transverse cut at 0.5 mm posterior to Hensen's node of stage 4 blastoderm, remain incapable of differentiation when grown in a variety of media or by chorioallontoic grafting technique. When combined with the region anterior to the streak, including Hensen's node, however, the PNP would undergo normal differentiation similar to the embryonic axial structures[1-3], suggesting that information might have been transferred from one tissue to another. Later studies by Butros[2] and Niu and coworkers[4,5] have shown that the PNP explants could be induced to develop into specific tissues, such as pulsating cardiac muscle tissues, when the explants were cultured in the presence of RNA isolated from the embryonic heart. The development was organ specific since RNA from kidney or thymus was incapable of inducing the heart formation[5]. To confirm this mode of differentiation in the PNP and to provide a meaningful biochemical interpretation to the phenomenon, we have begun studies examining the precise nature of the competent RNA and the sequence of events that leads to the formation of highly organised myofibrils. In a parallel study, we asked whether addition of exogenous cyclic AMP, which seems to be involved in control of morphological differentiation and biochemical changes in both normal and neoplastic cells (for review see ref. 6 and subsequent papers 7–15) would affect the development of the PNP in culture. Here we report that cyclic AMP, in the absence of exogenous RNA, can indeed produce specific morphological transformations, including the formation of heart-like pulsating tissues.

Fertile Leghorn chicken eggs from Spring Lake Farms, New Jersey, were incubated at 38 °C to obtain the definitive streak stage, stage 4 (ref. 16). The area opacua was trimmed off from the explanted blastoderms of the egg and the PNP was obtained by transecting the area pellucida at 0.6 mm behind Hensen's node to exclude totally the presumptive heart-forming region[17,18]. The PNPs collected from 20–30 eggs per experiment, were pooled together, and then divided randomly in batches of 3 each for *in vitro* cultivation. When the explants were cultured in the absence of cyclic AMP (control) the growth pattern of PNP was similar to that described previously[5,19]. The primitive streak disappeared after 24 h of incubation and patches of red blood cells appeared on the third day. No axial structures and twitching tissues were seen in any of the explants even after 10 d of incubation (Fig. 1*a*). The absence of twitching tissues in all the control explants (see Table 1) indicated
Fig. 1 Whole mounts of PNP cultured with or without cyclic AMP (0.5 mM). The cultivation was a modification of New's technique[31] as described earlier[32]. Three PNPs were placed on the yolk-free vitelline membrane (VM) previously mounted around a glass ring, with the epiblast in contact with the VM. After removing excess PC (Pannett-Compton) solution[32] the PNPs were carefully flattened on the VM. One millilitre of the nutritive medium (NM)[19] was then pipetted in each dish containing 3 PNP. The medium contained 50 U ml^{-1} of penicillin and 50 µg ml^{-1} of streptomycin. The pH of the final solution after adding the supplements was 7.6. Cyclic AMP (0.5 mM) was added directly to the medium. Incubation was done at 38 °C and the PNPs were examined at regular intervals. All operations were carried out in sterile conditions. The PNPs were examined at regular intervals with a binocular microscope for changes in growth, appearance of the pulsating tissues and general morphology. The PNPs were photographed after staining with haemotoxylin and eosin Y at times indicated. a, −cyclic AMP, 72 h incubation; b, + cyclic AMP 40 h incubation; c, + cyclic AMP, 72 h incubation; d, +cyclic AMP, 96 h incubation. RBCs, patches of red blood cells; PSG, primitive streak outgrowth; BA, beating area; CT, cardiac tube. Magnification ×30.

that transection at 0.6 mm posterior to the node did exclude the entire presumptive heart-forming region from the PNP. In contrast, the addition of cyclic AMP (0.5 mM) caused striking changes in growth and development of the PNP. Not only did the primitive streak persist during the early stages, but it eventually grew to be equal in length to the whole explant, and in addition, a median structural outgrowth (PSG) projecting from the anterior end of the streak became visible during the first 24 h of incubation. The site

of the outgrowth projection, that is, the anterior end of the primitive streak, was similar for all the cyclic AMP-induced PNPs. Further incubation resulted initially in the appearance of infrequent twitchings near the basal portion of the outgrowth (Fig. 1b) which changed on day four, into rhythmic and spontaneous pulsations resembling that of cardiac tissues in normal intact embryos. This was accompanied by a progressive digression of the PSG, which was first transformed into a beaded string-like structure breaking off eventually from the rest of the explant (Fig. 1c). After 4 d of incubation cardiac tubular structures with rhythmic pulsations were visible (Fig. 1d). The steady rate of pulsations lasted 2–4 d without supplementing the medium. An important difference between the cyclic AMP-induced growth of the nodeless streak and that of normal intact embryo was the absence of normal regression of the primitive streak in the former.

An ultrastructural examination of the PNPs (Fig. 2) revealed that typical epithelial, mesenchymal and erythroblastic cells were found in explants of both control and experimental groups. Scantily-dispersed endoplasmic reticulum, vesicular nuclei and a few mitochondria appeared to be the characteristic features of the undifferentiated PNP. However, all randomly selected PNPs grown with effective concentrations of cyclic AMP (see below) contained, in addition to the normal components, highly differentiated myoblasts which seemed to be similar in ultrastructural complements to the normal chick embryonic myocardial cells. Clearly evident were the

Table 1 Effect of cyclic AMP and analogues on differentiation in PNP

Additions	No. of PNP treated	No. of differentiated PNP*

No additions (control)	84†	0 (0%)

Details of culture condition were described in the legend to Fig. 1.

*Differentiation was characterised by the appearance of spontaneous and rhythmic pulsations after 96 h incubation. In addition, characteristic myofibrillar structures were found in all randomly-selected pulsating explants when examined in the electron microscope. None of the explants of control series or those treated with non-effective agents contained myofibrils.

†The number of PNP explants represents a cumulative total of several experiments.

orderly arranged myofibrils with intercellular apical junctions or intercalated disks as described previously[5,20]. These myofibrils were absent in the PNPs of control group and in those which did not differentiate into beating tissues. Measurements of the total protein content[21] using three
Fig. 2 Electron micrographs of cells of PNP after 96 h incubation with or without cyclic AMP. Electron microscopy was done in Dr M. Boublik's laboratory at the Roche Institute of Molecular Biology according to O'Brien *et al.*[34]. *a*, +cyclic AMP (0.5 mM); *b*, −cyclic AMP; Nu, nucleus; MF, myofibrils; Z, Z-bands; is, intercellular space; I, intercalated disk; Mt, mitochondria; G, Golgi body; Fi, filopodia; Me, mesenchyme.

PNP explants per assay, done in triplicate, revealed that each PNP of stage 4 blastoderm contained $9.0 \pm 1.0 \mu g$ protein, which increased to $21. \pm 0.7 \mu g$ after 4 d of incubation in the absence of cyclic AMP. However, the PNP which differentiated into beating tissues contained $30.6 \pm 1.3 \mu g$ per protein per explant. Thus, the formation of myofibrillar structures, the acquisition of spontaneous and rhythmic pulsations, the appearance of distinct morphological changes, such as the persistence of the primitive streak, and the increase in total protein content were all characteristic features of only those PNPs which received effective amounts of cyclic AMP and provided clear lines of evidence for a differentiative transition in the PNP.

Cyclic AMP, at 0.5 mM, was most effective, whereas concentrations below this level caused little or no differentiation (Table 1). Dibutyryl cyclic AMP, on the other hand, when used at similar concentrations appeared to be a poor inducer. Theophylline, which acts specifically as an inhibitor of phosphodiesterase and thereby increases the intracellular level of cyclic AMP[22], also induced differentiation similar in microscopical examination to that caused by cyclic AMP. Furthermore, a synergistic effect was clearly evident when non-effective concentrations of cyclic AMP (0.1 mM) and theophylline (0.5 mM) were added together to the culture medium. These results led us to speculate that changes in intracellular levels of cyclic AMP might be responsible for the specific morphogenetic transformations in the PNP.

Table 2 Endogenous levels of cyclic AMP in cultured PNP explants

Incubation Time (h)	Experiment	No additions	Cyclic AMP (Pmol μg⁻¹ protein) +cyclic AMP	+ADO	+THEO
0	1	0.019	0.023	0.020	0.026
	2	0.022	0.030	–	–

	2	–	0.460	0.066	0.088
48	1	0.058	0.730	0.040	–
	2	0.044	0.520	–	–
96	1	0.050	0.690	0.125	0.091

Endogenous levels of cyclic AMP were essentially determined according to Gilman[35] and Brown *et al.*[36] and as described in Amersham/Searle *Cyclic AMP Assay Kit*, TRK 432. Exogenous cyclic AMP, Ado (adenosine), or Theo (Theophylline), 0.5 mM each, were added directly to the culture medium (NM) and the PNPs were placed on top of the vitelline membrane (VM) as described in the legend to Fig. 1. At times indicated the explants were removed, washed 4 times with ice-cold Ringer's solution. Removal of extracellular cyclic AMP was indicated by no further decrease in cyclic AMP with additional washes. The PNPs were homogenised in 5% trichloroacetic acid. The precipitate recovered after centrifugation was used for protein determination[21] and the supernatant was extracted thoroughly with ether and dried by lyophilisation. The dried material was taken up in Tris-EDTA buffer for cyclic AMP determination. Three PNPs were used per assay and the assays were done in duplicate for each experiment. The numbers above represent an average of six PNPs for each time point.

This assumption was tested by (1) a direct estimation of endogenous cyclic AMP levels and (2) by the exogenous addition of adenosine which is known to cause an elevation of cyclic AMP levels in a variety of tissues[23-25], because of the direct activation of the enzyme adenylate cyclase by adenosine[26]. Intracellular cyclic AMP level was estimated as described in the legend to Table 2. The explants after incubation with exogenous cyclic AMP were washed 4 times with ice-cold Ringer's solution. Removal of all extracellular cyclic AMP was indicated by no further decrease in cyclic AMP with additional washes. When cyclic AMP was added to the culture medium, there was a 25-fold increase in the intracellular cyclic AMP level after 12 h incubation (Table 2). This increase represented about 70% of the total increase observed at 48 h incubation, which was the saturation level of cyclic AMP uptake. The 12-h-old explants were almost one-third in size and in protein content compared with those

cultured for 96 h. It would seem therefore that the uptake of cyclic AMP occurred predominantly during the early stages of incubation and was not directly related to the growth and increase in size of the explants

Addition of theophylline and adenosine to the culture medium also caused a significant increase in the intracellular cyclic AMP levels (Table 2). The increase was, however, substantially lower than that observed with exogenous cyclic AMP, but was apparently sufficient to cause the differentiative transition in the PNP (see Table 1). A specific feature of the adenosine effect is the fact that it can be abolished by theophylline (methylxanthine), which acts as a competitive inhibitor of adenosine[24,26,27]. As shown in Table 1, adenosine, but not guanosine, could mimic the effect of cyclic AMP. The concentration of adenosine required for an optimum effect was lower than that required for cyclic AMP. This might be due to a differential uptake of these compounds by the PNP in the culture conditions used. The adenosine-stimulated differentiation was blocked effectively by theophylline. The inhibition caused by theophylline was diminished when adenosine concentration was raised from 0.2 to 0.5 mM, indicating the competitive nature of these drugs. These effects of theophylline and adenosine on PNP were strikingly similar with those observed on cyclic AMP system in other tissues. Thus, the results taken together strongly suggested that the observed changes in the PNP growth and development were caused by modulations in intracellular levels of cyclic AMP.

The multiplicity of the effects caused by cyclic AMP was reflected by the formation of highly organised myofibrillar structures, acquisition of spontaneous pulsations and by the appearance of specific morphological changes described above. A recent report[30] has confirmed these findings and has shown that in addition to heart-like tissues, neural tissues, notochord and nephric tubules were also noted. The concentrations of cyclic nucleotides required, however, were 6–30-fold higher than those used in our studies. Reporter and Rosenquist[29] have previously reported that cyclic AMP levels in the precardiac mesodermal area in head-process stage of the chick embryo was about 20 times higher than in kidney-forming, liver mesoderm, and in neuro-epithelial ectoderm regions. The authors suggested that the regional differences in cyclic AMP concentrations may indicate the possible involvement of cyclic AMP, a presumed morphogen, in early chick embryonic development. We believe that there is a relationship between the state of development of the cultured PNP explants and the changes in cyclic AMP levels together with the cyclic AMP-associated properties of cells, such as the changes in membrane permeability assembly of microtubules, and so on. But the relationship between the exogenous RNA-induced mode of differentiation[3,4,5,36] and that caused by cyclic AMP is yet to be ascertained.

We thank Dr M. Boublik and Mr F. Jenkins for doing the electron-microscopic studies and Dr A. Blume for many helpful discussions. We also thank Mrs Dallas George for secretarial assistance.

Postnatal development of the synaptic organisation of the lateral geniculate nucleus in the kitten with unilateral eyelid closure

CLOSURE of the eyelids over one eye during a well defined period of susceptibility in kittens has been shown to result in severe structural changes of the nerve cells in the lateral geniculate nucleus[1,2]. Neurones in those parts of the lateral
Fig. 1 The change in proportion of the symmetric synapses with age in the glomeruli (a) and the extraglomerular neuropil (b) of the binocular parts of lamina A and A1 of the lateral geniculate nucleus in the normal kitten. The phase of rapid change occurs during the period of maximum susceptibility. Vertical bars indicate standard error; ●, lamina A, ○, lamina A1; thick part of the horizontal bar indicates period of maximum susceptibility and thin part the period of declining sensitivity.

geniculate nucleus which are related to the binocular visual field and which receive fibres from the closed eye are smaller than those in the laminae innervated from the open eye. The fact that cellular changes do not occur in the part of the nucleus related to the monocular visual field has led to the hypothesis that there is a process of competition or an imbalance between the neurones in the deprived and stimulated portions of the binocular parts of the laminae, whereas such competition is not present in the monocular segment[2,3]. We have examined the lateral geniculate nucleus with the electron microscope at different intervals extending through the period of susceptibility after monocular eyelid closure and in a parallel series of normally reared kittens.

In nine kittens the eyelids over one eye were sutured together at the time of eye opening at about 10 d of age, and these animals were allowed to survive for varying periods, the longest survival period being 100 d. These animals were perfused at 24 °C with a mixture of 4% paraformaldehyde and 1% glutaraldehyde after a brief washout with a balanced salt solution. The lateral geniculate nucleus of both sides was removed from the thalamus, cut coronally into three blocks and processed for electron microscopy. After examination of 1-μm thick sections stained with toluidine blue[4], ultrathin sections were cut including the optic radiation and adjoining parts of laminae A and A1 and from the monocular segment of lamina A. In all animals the sections were taken from the middle third of the anteroposterior extent of the nucleus, from about the middle of the mediolateral extent of laminae A and A1 and from the monocular segment[2] in the lateral part of lamina A.

A study of the monocularly deprived lateral geniculate nucleus with the electron microscope showed that the de-prived laminae underwent little qualitative change compared with the undeprived laminae, and as the differences in cell sizes are not so opparent in ultra-thin sections it was often not possible to determine which were the deprived and undeprived laminae. There was no change in the appearance of the cell somata and the constituent organelles, apart from a slight diminution in the amount of the granular endoplasmic reticulum, in the dendritic profiles, axons, axon terminals and glia; in particular the large retinal terminals showed no abnormalities either in their electron density or synaptic vesicle content. Thus, there is no evidence for degeneration either of the axons from the deprived retina, or of the constituent neurones of the nucleus, nor was there a glial reaction. In view of this unexpected absence of qualitative changes a quantitative study was made, and because of the evidence suggesting that the cells of the undeprived laminae in such experimental animals may have undergone some hypertrophy[3,5,6], it was considered necessary to compare the quantitative data in this series with corresponding data from the laminae in normal kittens of the same ages. The brains of nine normal kittens were therefore perfused in the same manner and ultra-thin sections for electron microscopy taken from corresponding parts of the lateral geniculate nucleus.

Within the glomeruli the numbers and proportions of the asymmetric and symmetric synapses were counted, and their postsynaptic profiles were recorded at each age. No attempt was made to differentiate between the symmetric contacts formed by axon terminals and presynaptic dendrites. About 25 glomeruli were sampled randomly from the binocular parts of each of the laminae of the lateral geniculate nucleus of both sides in the experimental brains, and of one side of the normal brains, and similar data from the monocular segments of lamina A were obtained. Between
Fig. 2 The change in proportion of symmetric synapses with age in the glomeruli (*a* and *b*) and in the extraglomerular neuropil (*c* and *d*) of the binocular segments of laminae A and A1 of the ipsilateral (*a* and *c*) and contralateral (*b* and *d*) lateral geniculate nucleus after monocular eyelid closure. On the ipsilateral side lamina A1 has been deprived, and on the contralateral side lamina A. ●, lamina A; ○, lamina A1.

100 and 150 synapses were classified into these categories in each lamina, the total sample amounting to approximately 10,000 synapses. These counts were made from micrographs at a magnification of 16,000. The proportions of these two types of synapses were also estimated in the extraglomerular neuropil, approximately the same number being sampled as in the glomeruli; they were classified at the time of study on the microscope.

Within the glomeruli of the normal kittens there is a phase of rapid increase in the proportion of the symmetric synapses from less than 10% at 20 d to between 35 and 40% at 55 d, with relatively little further change up to 110 d (Fig. 1a) In contrast, in the extraglomerular neuropil, there is a steep fall in the proportion of symmetric synapses from 25 to 15% between 20 and 55 d (Fig. 1b). These figures confirm the qualitative observations that between 20 and 55 d there is a differentiation of the profiles within glomeruli, especially an increase in the number of vesicle-filled presynaptic dendrites making symmetrical synapses; during this period the glomeruli also became more clearly segregated by their glial envelopes. The time course and degree of maturation finally attained is similar in both main laminae. The comparable data from the glomeruli and the neuropil from the experimental brains show no significant (two-tailed *t* test, *P*>0.05) differences in the rate of development between the laminae in the normal and experimental brains and between the deprived and undeprived laminae on the two sides of the same experimental brains (Fig. 2). The

Fig. 3 A comparison of the time course of the change in proportion of symmetric synapses (●) with the other morphological changes which occur in lamina A of the lateral geniculate nucleus and optic tract during postnatal development in the kitten. Cell size (□) from Garey *et al.*[8], synaptic density (■) from Cragg[10] and myelination of optic tract fibres (○) from Moore *et al.*[11]. Horizontal bar indicates period of susceptibility.

proportions of the two types of synapses within the glomeruli and the neuropil of the monocular segment follow the same course of development as the binocular segments and there are probably no significant differences (*P*>0.05) in the deprived and normal monocular segments.

An analysis has been made of the types of profiles post-synaptic to the asymmetric and symmetric synapses respectively within the glomeruli. At younger ages there are more relay cell dendrites receiving asymmetric synapses than presynaptic dendrites (for example, at 20 d 90% of the profiles postsynaptic to the asymmetric retinal boutons are relay cell dendrites), but in progressively older animals there is an increasing number of presynaptic dendrites receiving such synapses (at 70 d about 70% of the postsynaptic profiles are relay cell dendrites). This difference, however, may be more apparent than real because of the greater difficulty

in distinguishing between relay and presynaptic dendrites at earlier ages when the presynaptic dendrite is not so clearly differentiated. Similar comparisons cannot be made about the profiles postsynaptic to symmetric synapses because the number of presynaptic dendrites making synapses at younger ages is very small, and they are less definitely identifiable, but at 110 d the majority of the symmetric synapses, like the asymmetric synapses, are on the relay cell dendrites. No statistically significant differences (*P*>0.05) were found in the postsynaptic profiles between the monocular and binocular segments, nor between the laminae of normal brains and the undeprived and deprived laminae of the brains of the experimental animals of the same ages.

The numerical data used for the estimates of the proportions of the types of synapses and of the postsynaptic profiles have also been used to provide estimates of the mean numbers of synapses per glomerulus at different ages. These data confirm the qualitative impression that the number of symmetric synapses in a glomerulus increases with age (for example the mean number at 20 d is 0.33 (s.e. 0.47), whereas at 110 d it is 2.76 (s.e. 1.76) in lamina A; *P*<0.001). The mean number of retinal synapses does not show a significant change with age, so the explanation for the change in the proportions of the synapses that has already been noted is due mainly, and perhaps solely, to an increase in the number of symmetric synapses. The brains of the experimental series showed similar changes with age and significant differences (*P*>0.05) were not found between them and those of the normal brains.

These electron microscopic observations show that there is a marked degree of development of the synaptic organisation occurring during the period of susceptibility to effects of eyelid closure, but that there are no appreciable differences to be found between the nucleus in a normal brain and in those animals subjected to monocular eyelid closure. Thus, if the shrinkage of the neurones in the lateral geniculate nucleus seen with the light microscope is associated with alterations in the retinal terminals or in the synaptic organisation, it must be at a level more subtle than that studied here. The cell shrinkage may be related to features of the intrinsic organisation, such as reciprocal and serial synapses, or to changes in the number of synaptic vesicles within terminals. It may, on the other hand, not be related to change in the lateral geniculate nucleus, but at the site of termination of the geniculo-cortical fibres in the visual cortex[7,8]. The findings in the series of normal brains of a marked change in the proportions of synapses within glomeruli and the extraglomerular neuropil between the ages of 20 and 55 d is further evidence that the nucleus is undergoing a phase of rapid morphological development during the period of susceptibility to monocular deprivation. It has already been shown that during this period there is a rapid growth in the size of cell bodies within the nucleus[9], in the synaptic density[10], and in the degree of myelination of the incoming optic tract fibres[11] (Fig. 3). It is of interest that within the glomeruli the change in proportion is due to an increase in the number of symmetric terminals, which, on present evidence, arise from interneurones[12,13], whereas in the neuropil the asymmetric synapses increase relatively more and these are probably predominantly the terminals of cortico-geniculate axons and collaterals of geniculo-cortical relay cells[14,15]. A change, however in the proportion of intrinsic axons after monocular and binocular eyelid suture has been found in another major site of termination of retinal fibres, the superior colliculus in the rat, where the final phase of growth of intrinsic axons fails to occur after eyelid closure[16]. This presents a paradox that within the superior colliculus unilateral eyelid closure has an effect on the attainment of the mature synaptic organisation, although no appreciable shrinkage of cells has been found, yet in the lateral geniculate nucleus, where there is a marked shrinkage of the neurones, there does not seem

to be any accompanying change in the synaptic organisation.

Partial replacement of serum by selenite, transferrin, albumin and lecithin in haemopoietic cell cultures

CULTURE media for mammalian cells usually require supplementation with serum to supply as yet undefined needs. Because the requirements are likely to be multiple, it is difficult to distinguish biologically between the effects of nonspecific 'nutritional' factors in serum and those of specific regulatory factors. Partial replacement of serum in these systems by chemically defined substances supplying the nonspecific needs would therefore represent a significant advance towards the definition of such specific factors. We have examined the role of several serum components in cultures of freshly explanted haemopoietic cells with this goal in mind.

Red-cell precursors in freshly explanted mammalian bone marrow will proliferate to form colonies if the medium contains serum and the glycoprotein hormone erythropoietin[1,2]. Similarly, colony formation by granulocyte/macrophage precursors is dependent on serum as well as a specific glycoprotein colony-stimulating factor[3]. We decreased the concentration of serum in these cultures until growth was limited. The serum concentration was made the only variable by maintaining erythropoietin or colony-stimulating factor at high and non-limiting levels. A mixture of a large number of known serum constituents was added to the cultures and restored growth. Elimination of the components one by one then established which were active and which were not. Four components—sodium selenite, transferrin, bovine serum albumin (BSA) and lecithin—accounted for all the activity of the mixture. We demonstrate here that in combination these substances replace most of the serum required for granulocyte/macrophage and erythroid colony growth and also facilitate some granulocyte/macrophage proliferation without added serum.

Bone marrow cells from the femurs of BDF₁ mice were plated in modified Dulbecco's medium (legend Fig. 1) made viscous with methyl cellulose[2]. Erythroid colonies of eight or more cells were identified[2] after 2 d of incubation, and granulocyte/macrophage colonies of more than 100 cells were scored after 8 d.

In these conditions, maximum numbers of erythroid colonies required the addition of 30% foetal calf serum. When the serum concentration was decreased to 1%, no colonies formed (Table 1). At this serum concentration, selenite, BSA and transferrin added individually had little

effect, while in combination they stimulated the formation of large numbers of colonies. Addition of lecithin to this combination caused no further enhancement. Omission of either selenite, BSA or transferrin from the mixture resulted in a significant decrease in colony growth, while omission of serum almost completely abolished growth.

Maximum numbers of granulocyte/macrophage colonies ordinarily required the addition of 10–15% serum. When
Fig. 1 Dependence of colony formation on foetal calf serum concentration. *a*, Erythroid colonies, percentage of counts at 30% serum (240 per 10⁵ cells), 0.5 erythropoietin units per ml. ○, Nothing added; ●, supplemented with 0.75% BSA, 3.4×10^{-6} M transferrin $+ 1.6 \times 10^{-6}$ M FeCl₃, and 10^{-7} M Na₂SeO₃. *b*, Granulocyte/macrophage colonies, percentage of counts at 30% serum (126 per 10⁵ cells), plateau amounts of colony stimulating factor. ○, Nothing added; ●, supplemented with BSA, transferrin/FeCl₃, Na₂SeO₃ and 3×10^{-5} M egg lecithin. Bars indicate standard errors. Cells were cultured at 10⁵ per ml in Dulbecco's modified Eagle's MEM (Gibco H21) containing 0.8% methyl cellulose and supplemented with 10^{-4} M α-thioglycerol plus the following (µg ml⁻¹): L-alanine (25), L-asparagine.H₂O (50), L-aspartic acid (30), L-cysteine (70), L-glutamic acid (75), L-proline (40), Na pyruvate (110), vitamin B₁₂ (0.025) and biotin (0.03). Human urinary erythropoietin was adsorbed on to benzoic acid and further purified on DEAE cellulose[4] and Sephadex G-100 (ref. 2). Colony-stimulating factor from serum-free mouse kidney cell conditioned medium[5] was partially purified by two passages over Sephadex G-150. BSA (Behringwerke, electrophoretically pure) was deionised over a mixed bed ion-exchange resin[6], charcoal (Norit A) extracted[7] (pH 3, 55 °C, 30 min) and chromatographed on an AcA 34 gel column to isolate the monomeric form. Human transferrin (Behringwerke) was further purified on AcA 34 and prepared as a 125× stock (38 mg lyophilised transferrin $+ 48$ µg FeCl₃.6H₂O per ml) in Dulbecco's medium. Na₂SeO₃ (Merck) was prepared as a 125× stock solution (2.2 µg ml⁻¹) in Dulbecco's medium containing 5% BSA. Egg lecithin (BDH, > 95%) was dissolved in propylene glycol (25 mg ml⁻¹) and diluted 10-fold to a 125× stock solution in Dulbecco's medium containing 5% BSA. Plate concentrations of propylene glycol (0.08%) were not inhibitory. Foetal calf serum was used without treatment.

Table 1 Effect of BSA, transferrin (Tf) and selenite (Se) on erythroid colony counts

Addition	Colonies per 10⁵ nucleated cells
30% Foetal calf serum (FCS)	353 ± 13*
1% FCS	0
1% FCS, Se	6 ± 3
1% FCS, BSA	13 ± 5
1% FCS, Tf	4 ± 2
1% FCS, Se, BSA, Tf	232 ± 9

1% FCS, Se, — , Tf	42 ± 7
1% FCS, Se, BSA, —	67 ± 10

Concentrations of BSA, Tf and Se were as in Fig 1.
*Standard error.

serum was eliminated, no colonies formed (Table 2). Selenite, BSA, transferrin or lecithin had no effect when added individually to the serum-free medium. When added in combination, however, they stimulated growth of significant numbers of colonies. Although the colonies obtained in these conditions were generally smaller than those obtained with 15% serum, many contained at least 1,000 cells and were visible to the unaided eye. Omission of either BSA or transferrin from the mixture eliminated colony formation entirely and colony numbers were also reproducibly lower in the absence of selenite or lecithin.

The serum-sparing effect of these substances is demonstrated in Fig. 1. The addition of selenite, BSA and transferrin reduced the serum required for maximum numbers of erythroid colonies from 30 to 2.5%. With the further addition of lecithin, the serum requirement for maximum granulocyte/macrophage colony growth was reduced from 10 to 2.5%. Again it was interesting that whereas erythroid colony formation was dependent on serum even in the presence of these substances, some granulocyte/macrophage colony formation was possible in the absence of serum.

Table 2 Effect of BSA, Tf, Se and egg lecithin (lec) on granulocyte–macrophage colony counts

Addition		Colonies per 10⁵ nucleated cells
15% FCS,		146 ± 9*

Se,	BSA, Tf, —	24 ± 3

BSA was used in a concentration of 1.2%.
Concentrations of Tf and Se were as for Fig 1.
*Standard error.

It is possible that the activities demonstrated for the proteins BSA and transferrin were attributable to trace impurities. Efforts were made to diminish this possibility by further purification of supplied materials (legend Fig. 1). Transferrin activity was not replaced by the equivalent amount of Fe^{3+} alone, nor was its activity reduced after gel permeation chromatography. Acrylamide slab gel electrophoresis[8] of purified BSA and transferrin in denaturing conditions (0.1% SDS, 0.1% β-mercaptoethanol, 2 µg of protein per slot) revealed only a single Coomassie brilliant blue-stainable band in both instances.

We anticipate that the active substances reported here will prove to have similar nonspecific, serum-replacing activity in cultures of various other cells and tissues. Selenium, present in serum at a concentration of

1.4×10^{-7} M (ref. 9), has long been recognised as an essential trace element in whole animal studies[10], and McKeehan et al. demonstrated it to be a requirement for growth of human fibroblasts in culture[11]. The selenium-containing enzyme glutathione peroxidase is known to be present in leukocytes[12] as well as erythrocytes[13]. The requirement for transferrin by maturing red cells is not surprising, since this iron-transporting protein, present in serum at 4×10^{-5} M (ref. 14), is known to be the major source of iron for these cells. It was unexpected, however, that transferrin should also prove necessary for growth of granulocyte/macrophage precursors. Taken together with the observations that transferrin has a role in the proliferative response of human lymphocytes to PHA[15], and in the growth of fibroblasts and pituitary cells in culture[16], the finding suggests a much wider requirement for this protein than has been recognised. Among numerous conceivable functions of albumin, we consider the likeliest to be that of a buffer for components of the medium present in inhibitory amounts. This suggestion predicts that the albumin requirement would diminish if the numerous defined components of the culture medium were adjusted to optimum levels.

The straightforward interpretation of our observations is that a major role of serum in culture is to provide selenium, transferrin, albumin and lipids to the medium. Our results do not, however, exclude the possibility that these entities simply substitute for other unrelated substances provided by serum. Several agents that were expected to show activity did not enhance colony formation at low serum concentrations, provided that selenite, transferrin, albumin and lecithin were present and that erythropoietin and colony-stimulating factor were maintained at non-limiting levels. Among those tested were dexamethasone (2.5×10^{-10} M), insulin (2.5×10^{-8} M), testosterone (10^{-8} M), etiocholanolone and fluoxymesterone (3×10^{-7} M), prostaglandins E_1, E_2 and $F_2\alpha$ (5×10^{-9} M), $ZnCl_2$ (10^{-7} M), and cholesterol (3×10^{-7} M).

Our observations have important technical implications. First, inclusion in culture medium of the active substances reported here greatly reduces the quantities of serum required, and in our experience has transformed several serum lots from inadequate to fully active. More important, we expect their routine inclusion in medium to simplify the search for more specific biologically active substances in conditioned media and serum by reducing the number of variables in the system.

Cell contact induces an increase in pinocytotic rate in cultured epithelial cells

ENDOCYTOSIS is the process by which cells internalise part of the plasma membrane in association with extracellular components: they engulf large particles by phagocytosis and internalise components in the fluid phase by pinocytosis. Discrimination of phagocytosis from pinocytosis has been based on the size of the particle and the amount of energy required to internalise it, phagocytosis being inhibited more readily by metabolic poisons than pinocytosis[1-3]. This is consistent with the view that more energy is required to internalise a large surface area than is needed for a small surface area. Vasiliev et al.[4] described "contact inhibition of phagocytosis": when cultured epithelial cells, but not fibroblasts, became confluent, the rate of phago-cytosis decreased considerably. I report here that confluent cultured epithelial cells are not inhibited in their ability to undergo pinocytosis, but exhibit a greater rate of pinocytosis than do non-confluent cells. This difference is not due to diffusable factors, but is the result of cell contact.

Permanent lines of cultured epithelial cells of human (HeLa) or monkey origin (Mk$_2$) were grown as monolayers on plastic tissue culture dishes and maintained in Eagle's MEM containing 10% calf serum, penicillin (5 U ml^{-1}) and streptomycin (2 U ml^{-1}). Cells were passaged routinely every 4-5 d. Pinocytosis was measured using horse-radish peroxidase (HP) according to the method of Steinman et al.[5,6], or ^{125}I-albumin by Rhyser's procedure[7]. HeLa cells took up HP linearly with respect to both concentration (not shown) and time (Fig. 1). The level of endogenous peroxidase activity in HeLa cells was essentially unmeasurable (<0.1 ng enzyme per mg cell protein), and washing removed all non-internalised enzyme. These results support the conclusions of Steinman et al.[5,6] on the value of HP as a pinocytotic marker. I also observed that when the uptake of enzyme was calculated on either a per protein (Fig. 1a) or a per cell basis (not shown), cultures of HeLa cells plated at higher densities exhibited greater rates of uptake than those of lower densities. In spite of slight differences in the

absolute amount of HP taken up in different experiments (10-20%), there was a consistent difference in the rate of uptake between cultures seeded at different densities. This is demonstrated more strongly in Fig. 2, in which a wider range of cell densities was used. Similar differences in the rate of uptake were observed whether marker was presented to cells in fresh medium or medium conditioned by exposure to confluent cells for 3 d.

Mk$_2$ cells are derived from a pool of normal rhesus monkey kidneys, and unlike HeLa cells, they have several characteristics typical of normal cells, such as density-dependent inhibition of growth and macromolecular synthesis, and an inability to grow in either suspension or soft agar[8]. I also observed that as Mk$_2$ cultures became more dense, the rate of pinocytosis increased, and stabilised only as they reached their saturation density (data not shown). Similar results were obtained if pinocytosis was assessed on a per cell instead of a per protein basis. Thus, a density-dependent increase in the rate of pino-cytosis is not unique to HeLa cells.
Fig. 2 Uptake of HP by different densities of HeLa cells. Different numbers of HeLa cells were seeded on plates 72 h before the experiment. Monolayers were incubated in medium containing HP (1 mg ml^{-1}) for 3 h and then processed as described for Fig. 1. Duplicate samples were taken and cells were counted.

The difference in rate of uptake was independent of HP. When iodinated albumin was used as a pinocytotic marker, cultures of HeLa or Mk$_2$ cells at a higher density exhibited a greater rate of uptake than those at a lower density.

To establish that the difference in accumulation of pinocytotic markers was the result of a difference in uptake, I measured the rate of intracellular inactivation of HP. Cultures of HeLa cells plated at different densities and exhibiting a twofold difference in uptake inactivated the enzyme at the same rate (Fig. 3). In both cases, the enzyme was inactivated with single exponential kinetics (correlation coefficient >95%), yielding a half life of 6.5 h. HeLa cells plated at different densities degrade ^{125}I-albumin at similar rates, yielding a half life of 16.4 h. Thus, differences in the rate of accumulation reflect differences in the rate of uptake rather than degradation.

The progressive increase in the rate of pinocytosis as cell density increased (Fig. 2) was independent of cell number but not cell density as the following experiment showed. Using small glass cylinders of different diameter, I plated a constant number of cells per dish. This procedure yields different cell densities, thus modifying the degree of cell-cell contact. I found that an increase in cell density gave rise to an increase in pino-cytosis regardless of whether the pinocytotic marker was presented to cells in fresh medium or medium conditioned by exposure to confluent monolayers. Thus, an increase in the degree of cell contact induced an increase in the rate of pino-cytosis.

As the difference between rates of uptake by cells plated at different densities was the same in fresh and conditioned

Fig. 1 Cultures of different numbers of HeLa cells were seeded 48 h before the experiment. Cells were then incubated in complete medium containing HP (1 mg ml^{-1}) for the times specified. After incubation the monolayers were washed eight times with cold phosphate-buffered saline (PBS), incubated in PBS at 4 °C for 20 min and washed four more times. The monolayers were then solubilised with 0.1% Triton X-100 and HP was assayed as before[5]. Duplicate cultures were trypsinised and cells were counted. Protein concentrations were determined by the procedure of Lowry et al.[10]. Each point is the average of triplicate samples. The standard error of the mean is 5-8% for both cell number and enzyme assay. $\triangle$, 1.25 × 10^6 cells per plate; $\bigcirc$, 0.75 × 10^6 cells per plate.

Fig. 3 Rate of degradation of internalised HP. Monolayers of cells were incubated with HP (1 mg ml^{-1}) for 20 h and then washed six times with cold MEM and twice with warm MEM + 10% calf serum. At the times specified, monolayers were collected and enzyme was assayed as described for Fig. 1. The symbols represent experimental data, the line is a computer-determined best fit to the data. At the end of the experiment the cultures had densities of 1.41 ($\triangle$) and 3.81 × 10^6 ($\bigcirc$) cells per plate.

medium, I suggest that diffusable factors are not responsible for the difference in the rate of pinocytosis. I found that if cellular levels of cyclic AMP were increased by addition of dibutyryl cyclic AMP (1 mM) or caffeine (10 mM), the rate of pinocytosis in sparse cultures was not affected.

The change in rate of pinocytosis in HeLa and Mk$_2$ cells occurs before any overt change in growth rate. For example, Mk$_2$ cells divide at a constant rate with a generation time of 42 h until a density of 5.5 × 10^5 cells per cm^2 is reached[8]. HeLa cells divide at a constant rate until a cell density of 1.2 × 10^6 cells per cm^2 is reached, after which the rate of division decreases by 80–90% (my unpublished results). But before any change in growth rate, the rate of pinocytosis may change by a factor of four to six. This suggests that changes in the rate of pinocytosis are independent of inhibition of cell division.

The cell types used in this study were of epithelial origin. It has been demonstrated, however, that L cells[6] and sarcoma 180 cells (H.J.P. Rhyser, personal communication) of fibroblast origin exhibit a density-induced increase in pinocytosis. Apart from the Mk$_2$ cell all these cells are derived from established tumours. Although Mk$_2$ has several characteristics typical of normal cells, it has been maintained in culture for 16 yr; perhaps the density-dependent increase in pinocytosis results from adaptation to tissue culture. I am investigating whether primary cultures of epithelial cells exhibit a density-dependent increase in pinocytosis.

Using either polystyrene beads (1.10 µm in diameter) or Oil red 0–albumin emulsions, I have not been able to quantify the rate of phagocytosis in either non-confluent or confluent monolayers incubated for up to 4 h. Thus I cannot comment directly on "contact inhibition of phagocytosis". It may be that the difference in phagocytosis is related to a change in the adhesive characteristics of the membranes of confluent cells, as suggested previously[4,9]. Whether or not "contact inhibition of phagocytosis" can be confirmed, my results show that it is not due to the inability of the cell to internalise plasma membrane. Contrary to expectation, the occurrence of cell–cell contact seems to enhance at least one membrane function.

Presence of membrane particles in freeze-etched bovine olfactory cilia

WHEN an odorant molecule stimulates an olfactory receptor cell the electrical changes which are set up must result from some kind of interaction between the stimulant and the cell surface. Various theories of olfaction have favoured either lipids[1] or proteins[2], as the principal site of odorant reception. Experiments distinguishing unequivocally between these alternatives have yet to be performed[3], but there is growing evidence that the receptor is proteinaceous[4,5].

Two other protein-containing receptors that have been extensively explored are rhodopsin[6] and the acetycholine receptors of skeletal muscle[7] and electroplax origin[8]. All of these have been visualised in freeze-fractured preparations by electron microscopy as being related to particles 8–12 nm

Fig. 1 Freeze-etch replica of the surface of the bovine olfactory epithelium showing two receptor endings (re) and the apex of a supporting cell (sc). Note the broken basal portions of cilia at the surface of the sensory ending on the right, and two vertically cleaved cilia on the left (× 25,000).

Fig. 2 Detail of Fig. 1 showing membrane features of two sensory cilia. In the cilium on the right, numerous membrane particles and part of a ciliary necklace (arrow) are visible on the exposed PF face. In contrast the EF face shown in the cilium to the left, bears few or no membrane particles ($\times$90,000).

across, embedded in the cell membranes of the sensory surfaces. If the olfactory receptor sites are indeed of a similar nature, one also might expect to find membrane particles in the sensory cilia of olfactory receptor cells, but until now attempts to observe them have been unsuccessful[9-11]. In this letter we report the discovery of high densities of membrane particles in the sensory cilia of bovine olfactory cells.

Heads of male calves (1 month old) were longitudinally bisected and olfactory tissue on the cribiform plate and ethmoturbinates fixed *in situ* with ice-cold Karnovsky's fixative[12] buffered at pH 7.0, for 1 h, then excised and placed in fresh fixative for 2 h. Tissue from the neighbouring ciliated non-sensory respiratory mucosa was also treated in the same way for control purposes. After washing in buffer, small pieces of tissue were soaked in 20% cacodylate-buffered glycerol (pH 7.0) containing 0.01% $CaCl_2$ for 24 h and were then fractured, etched and replicated in a Balzers GA-6 freeze etching device according to standard techniques[13]. Replicas were observed in an Hitachi 125E electron microscope at 125 kV. The nomenclature recently proposed by Branton *et al.*[14] will be used in this description. In the figures, shadows appear white.

In addition to studies of freeze-etched material, pieces of tissue were also examined in sections by routine transmission and scanning electron microscopy for comparison with the freeze-etched material. In this way, the olfactory and non-olfactory tissue could be unequivocally distinguished in both types of preparation.

The general structure of the sensory tissue of the ox is similar to that of other mammals which have been studied with the electron microscope[15]. The surface of the olfactory epithelium is formed partly by the terminal knobs of sensory dendrites bearing an average of 17 cilia which possess short proximal portions averaging 1.7 μm long by 0.2 μm wide, tapering to long trailing distal regions 0.08 μm in diameter and at least 30 μm long; these distal portions are expanded

occasionally to form vesicles averaging 0.6 μm across. The supporting cells surround and separate the receptor cells, and bear at their apices abundant microvilli which extend almost to the surface of the mucus layer covering the epithelium, the thickness of this layer being about 5 μm. The neighbouring respiratory epithelium consists mainly of non-sensory columnar epithelial cells bearing motile cilia and a few microvilli, with occasional goblet cells interspersed.

Freeze fractured and etched olfactory epithelia showed a pattern of recognisable sensory endings and cilia, and the surfaces of supporting cells. Membrane particles, 8–12 nm across, were present in abundance on the olfactory cilia, at the PF-face (A face) of the membrane (Figs 1–3), and over the whole of the exposed sensory surface of the dendrite. Particles were more numerous on the narrow distal ends of the cilia (6,000 μm^{-2}) than on the more proximal ends (4,300 μm^{-2}) or on the dendrite ending itself (3,400 μm^{-2}); the mean density for the surface of the sensory ending was 5,200 μm^{-2}.
Fig. 3 The tapering distal portion of an olfactory cilium covered in closely packed membrane particles. The ring-like structure in the centre is a surface irregularity ($\times$190,000).

From measurements made on transmission and scanning electron micrographs it was calculated that each sensory ending had a surface area of at least 160 μm^2, bearing approximately 10^6 particles. The number of endings per cm^2 of epithelial surface was 5$\times$10^6. Allowing for the volume occupied by receptor and supporting cell processes, the concentration of particles within the confines of the 5 μm layer of mucus at the epithelial surface was estimated to be 10^{19} l^{-1}, which represents a molarity of 2$\times$10^{-5} if each particle is assumed to be a single molecule.

Close to the proximal end of each olfactory cilium, six rows of particles, corresponding to the "necklace" formation in other cilia[16], could be distinguished. In contrast the cilia of the neighbouring non-sensory respiratory epithelium bore few membrane particles (average 300 m^{-2}) although the proximal 'necklace' was present, as described by other authors[17] (Fig. 4). Membrane particles were, however, seen on the short microvilli interspersed among these cilia. Few particles were found at the EF-face (B face) of the membranes of either the olfactory or non-olfactory tissues.

The particles found in the sarcolemma at neuromuscular junctions and in the rod outer segment are similar in packing density to those described here[6,7]. Membrane particles have been shown in several cases to be proteinaceous[18] and

it can be predicted that the olfactory ciliary membranes are appreciably richer in protein than, for example, those of the motile respiratory cilia. Although the particles could represent ion conductance channels, or some purely structural feature, it seems reasonable to suppose they might also be the receptor sites responsible for binding odorants. Their presence in such high densities may be correlated with the sensitivity of the sensory cells to low concentrations of odorants, and also with the hypothesis that many classes of receptor site, responding to different odorants, may be present on individual sensory cells[19].

Note added in proof: Similar particles have recently been found in mouse olfactory cilia[20].

Inhibition of PEP-carboxykinase in rat liver by polychlorinated biphenyl

POLYCHLORINATED biphenyls (PCBs) are widely used industrial chemicals which have found their way into the environment, where they have been detected in rainwater, in many species of birds and fish and in human tissues. PCBs accumulate in the body's fat tissues, where they apparently degrade very slowly under natural conditions[1], but recently it has been found[2] that PCBs may act as carcinogens. The detailed actions of PCBs inside the body, such as their effects on carbohydrate, lipid or protein metabolism, are relatively unknown although they have been shown to alter the liver cell in mouse and monkey[3], to affect the immune system[4] and to alter the activity of microsomal and other enzyme systems[5–8]. We have studied the *in vivo* effect of PCBs on the activity of two regulatory
Fig. 1 Effects of PCB (Clophen T64) on PEPCK and FDPase activities in rat liver and on the level of blood glucose. Female rats (Sprague–Dawley, 150–170 g) were used in the experiments. PCB diet was prepared by thoroughly mixing (starmix) 500 g of normal pellets (Eggersmann, Rinteln) with 10 ml of a solution of PCB (Clophen T64) in ethanol giving a final concentration of 0.05% of PCB in the diet. The powder was pasted with water, pellets were formed and dried for 2 d at 37 °C in an oven. The diet for control animals was treated in exactly the same way but without PCB. After the indicated time intervals, livers of 4 rats from each group were removed under ether anaesthesia, homogenised individually in a Potter homogeniser at 0 °C for 1 min using 2 g of liver tissue per 10 ml of 0.25 M sucrose solution. The homogenate was centrifuged for 30 min at 105,000g. PEPCK activity[11] and FDPase activity[12] were determined in the supernatant. Blood (0.10 ml) was taken from the aorta descens during removal of the liver, and blood glucose was determined with glucose oxidase[13]. Enzyme activities and content of blood glucose from control animals were set at 100%. $\times$, PCB in liver; $\blacktriangle$, food intake; $\triangle$, blood glucose; $\bigcirc$, FDPase; $\bullet$, PEPCK.

enzymes of gluconeogenesis, phosphopenol-pyruvate carboxykinase (PEPCK) and fructose-1, 6-diphosphatase (FDPase), respectively, in rat liver.

As can be seen from Fig. 1, a diet containing 0.05% PCB (Clophen T64, 60% Cl) diminished the activity of PEPCK by about 50% within a feeding period of 7 d. FDPase activity and the content of blood glucose were also influenced by PCB, but to a much lower extent. Furthermore, the food intake of the animals was not markedly altered by PCB when given in this concentration. During the experimental period the content of PCB in the liver tissue increased from 0.145 (control) to 110 µg per g wet liver. Thus, an *in vivo* content of 70.5 p.p.m. of PCB in the liver lowered the activity of PEPCK to one half of its original activity.

Table 1 Effects of various chlorinated compounds on the activities of PEPCK and FDPase and on the content of blood glucose in rat liver

Dietary addition (0.05%, 7 d)	PEPCK	FDPase	Blood glucose
		(% of control)	
None	100	100	100
Biphenyl	91	101	79
2-Chlorbiphenyl (19% Cl)	119	102	104
Clophen A30 (42% Cl)	66	110	97
Clophen A50 (54% Cl)	53	75	78
Clophen A60 (60% Cl)	51	84	99
Hexachlorobenzene	106	96	100

Rats were fed a normal diet (control), a diet with biphenyl (0.05%) or with various chlorinated compounds (0.05%) for 7 d. Preparation of the diet and experimental details are given in the legend to Fig. 1.

Figure 2 shows the effect of increasing concentrations of PCB in the food after a feeding period of 4 d. A dose of 0.01–0.05% PCB reduced the activity of PEPCK, but did not alter the activity of FDPase, the level of blood glucose and the food intake. Higher concentrations of PCB, however, were obviously toxic because the food intake was reduced and the animals partially fasted. Consequently, PEPCK activity increased in these conditions, since the activity of this enzyme is very sensitive to the animals' nutritional state (see Table 2 and ref. 9). The level of blood glucose and FDPase activity were also lowered by higher concentrations of PCB.

Other chlorinated compounds which are chemically related to PCBs or are concomitants (hexachlorobenzene) were also tested for their *in vivo* ability to influence the activity of PEPCK, FDPase and the level of blood glucose (Table 1). From these compounds PCBs with high chlorine content were most effective on PEPCK, whereas the effect on FDPase activity and on the level of blood glucose varied.

Gluconeogenic conditions such as fasting or feeding a protein diet (poor in carbohydrate) increases PEPCK activity[9]. As is shown in Table 2, after fasting or protein diet PEPCK activity was increased 4.5-fold and threefold, respectively. When PCB was added to the normal diet, the induction rate after
Fig. 2 Effect of increasing PCB concentration on PEPCK and FDPase activities in rat liver. Rats were fed a diet with PCB (Clophen T64) for 4 d. Diet was prepared as described in the legend to Fig. 1, but PCB concentration was varied. Further details see legend to Fig. 1. Symbols as in Fig. 1.

fasting was only twofold and in rats fed a protein diet containing PCB the increase of PEPCK activity was only 1.8-fold. Thus, PCB severely disturbs the ability of the rats to adapt PEPCK activity to gluconeogenic conditions.

Although PCBs are chemically almost inert substances, these compounds nonetheless can alter intermediary metabolism, that is gluconeogenesis. Most determinations described here were carried out between 4 and 7 d on PCB diet (Fig. 2 and Table 1, respectively). This corresponds to an *in vivo* PCB concentration in the liver of about 55–70 µg PCB per g wet liver tissue (see Fig. 1), being in the range of the concentration of physiological substrates. One can suggest, therefore, that PCBs do not act on PEPCK itself but somehow affect its regulation. Since PEPCK activity is closely connected with the level of cyclic AMP and hormones[10], these would be good candidates for further investigations on the mechanism of action of PCBs on intermediary metabolism.

We thank W. Sümmermann and N. Schwaak for the determinations of PCB contents in liver tissue.

Two-gene control of T-helper cell induction

THE major histocompatibility complex (MHC) of mouse, man and other species has attracted much attention recently, and that of the mouse is perhaps the most precisely studied mammalian genetic region (reviewed in refs 1–3). Within the space of 0.5 centimorgans are genes coding for transplantation antigens present on essentially all cells (H-2K and H-2D); genes influencing immune responses ("immune response or *Ir* genes"); genes coding for surface alloantigens of restricted tissue distribution (immune response gene region associated antigens or Ia antigens); genes influencing cell interactions, the production of factors and stimulation in the mixed lymphocyte reaction (all in the I region and its subregions I-A, I-B, I-C and so on), as well as genes controlling serum proteins related to complement (S region), and red-cell antigens. Although the products of some of these genetic regions are clear (for example, of the H-2D or H-2K loci) this is not the case for the I region which influences many immune functions, such as delayed hypersensitivity[4] and antibody production[5]. One group of products of the I region genes constitutes the Ia antigens which have been defined by alloantisera[6,7]. Other products of these genes are still elusive, and some authors have even suggested that I region gene products are antigen-specific receptors on T cells[8,9].

Recently, it was found that the I region influenced the induction of helper cells, *in vitro*[10]. To induce T-helper cells in our *in vitro* system[11], macrophages are required[12,13], and with soluble antigens the interaction between T cells and macrophages required genetic similarity in the I-A subregion of the H-2 complex[10]. In the mouse, unlike the guinea pig[14] interaction did not depend on direct contact between T cells and macrophages[12], and was mediated by at least two factors[10]. (1) A genetically related macrophage factor (GRF) is obtained from antigen-treated macrophages and generates T-helper cells in the absence of macrophages or additional antigen, but only if the macrophage releasing GRF and the T cells are similar at the I-A subregion of the H-2 complex. (2) A nonspecific macrophage factor (NMF), obtained from macrophages incubated without antigen, is not genetically restricted and induces T-helper cells in the absence of macrophages but only with particulate antigens[10]. We have characterised the immunochemical nature of GRF and found that it consists of I
Fig. 1 Evidence for a receptor for GRF on lymphoid cells but not on macrophages. CBA GRF$_{KLH}$ (1 ml) was incubated with either 1×10^8 nylon wool-purified T cells from CBA spleen (T) or with 6×10^7 macrophages (M) (purified by irradiation with 2,000R and adherence to plastic) for 1 h at room temperature. After removal of the cells by centrifugation the adsorbed GRF were added to 15×10^6 nylon wool-purified CBA T cells in a concentration of either 5 or 10% and incubated as described in the legend to Table 1. After 4 d, 2×10^6 living cells from each culture were added to 15×10^6 CBA spleen cells and incubated with TNP-KLH (0.1 µg ml^{-1}). Four days later the anti-DNP-response was measured. The dotted line represents the background (15×10^6 spleen cells and TNP-KLH, but no helper cells added). Five experiments of this type have been performed with analogous results. The vertical bars represent the standard error of the arithmetical mean of three independent cultures. To exclude the presence of receptors on B cells, anti-θ-treated and complement-treated spleen cells, cleared of dead cells by low ionic strength buffer[20] were used (viability >95%); 10^6 B cells per ml did not remove GRF (for example, in a typical experiment CBAT+GRF: 597 AFC per culture, GRF adsorbed B cells: 480, GRF adsorbed T cells: 47).

Table 1 GRF contains I-A subregion-coded products

CBA GRF$_{KLH}$	Immunoadsorbents		S/N%	Anti-DNP-response (AFC±s.e.) first eluate/acid eluate	
−	—		—	18±16

+			15	373±23	27±12

GRF obtained from CBA macrophages by incubating with keyhole limpet haemocyanin (KLH, 10 µg per 5×10^6 cells) for 4 d (CBA GRF $_{KLH}$) were passed over columns containing Sepharose 2B (1 ml of GRF per ml of Sepharose) conjugated with the immunoglobulin fractions of antisera directed against the K^k, I-A^k, I-B^k or I-C^k or ^{d} subregion of the H-2 complex (first eluate). After washing, the immunoadsorbents were treated with 1 ml of Sørensen's glycine buffer, pH 2,4; the eluates were neutralised immediately and dialysed against phosphate-buffered saline, pH 7.2 (acid eluate). 'First and acid eluates' were tested in different concentration for their helper-cell-inducing capacity by incubating with 15×10^6 nylon wool-purified CBA T cells for 4 d in Marbrook type flasks as described in detail elsewhere[11,12,13]. Living cells (2×10^6) from each culture (which include helper cells) were then added to 15×10^6 CBA spleen cells and trinitrophenylated KLH(TNP-KLH, 0.1 µg ml^{-1}), and 4 d later the anti-dinitrophenyl (DNP)-response was measured by the plaque forming ability of the B cells against DNP or TNP (which cross react) coated sheep red blood cells (SRBC). The results are given as arithmetic means of the DNP-AFC (antibody forming cells)±s.e. for three independent cultures. Specific AFC are enumerated by subtracting the number of plaques obtained with SRBC from that obtained with DNP-SRBC. The controls include 15×10^6 spleen cells incubated with either TNP-KLH (28±17), or DNP-polyacrylamide beads 3% (1372±175) or no antigen (12±11). (B10.A(4R) × 129) F, anti-B10.A(2R) antiserum (Anti-I-C $^{k\,\cdot\,d}$) was also tested on B10.D2 GRF(H-2^d). It did not adsorb GRF.

region coded products (Ia antigen) complexed with small antigenic fragments with a total molecular weight of 50,000–60,000 (ref. 16). Since Ia antigens are coded for in the I region (which also contains "immune response genes") we thought that more detailed knowledge about the mechanism of action of GRF might reveal information about helper-cell induction and perhaps how immune response genes work. We have therefore studied the mechanism of binding of GRF to T cells, and report here that at least two genes, located in the I-A subregion, influence helper-cell induction. One of these genes, expressed in macrophages, controls the Ia product of GRF, and the other, expressed on T cells, controls a structure which is the receptor for GRF. This receptor does not react with anti-Ia sera and is thus distinct from conventional Ia antigen.

Though as a result of genetic experiments T cell–macrophage interaction had been mapped in the I-A subregion[10], and GRF, which is one component of this interaction, was serologically shown to be an I region product[16], it was not clear whether GRF was indeed an I-A region product or whether the receptor for GRF was I-A-controlled. Using more specific sera, directed against the H-2K^k, I-A^k, I-B^k and I-C^k regions of the *H-2* complex, it was possible to show that the gene(s) responsible for GRF lie in the I-A subregion (Table 1). The evidence for this is that only immunoadsorbents made with anti-I-A^k sera adsorbed out the activity of GRF obtained from CBA macrophages. The adsorbed activity was recovered by acid treatment of the immunoadsorbents, further demonstrating the specificity of the adsorption. An analogous mapping of the genes for GRF in the I-A subregion of other haplotypes (for example, I-A^b or I-A^d) was not possible for lack of specific appropriate anti-I-A region antisera.

We next investigated the interaction of GRF with T cells resulting in the activation of the latter to become specific helper cells. A simple explanation of this interaction would be binding of GRF by a receptor on helper-cell precursors. To test this, GRF was incubated with either T cells, B cells (10^8 cells per ml of GRF) or macrophages (6 × 10^7 cells per ml) at room temperature (RT) for 1 h. Then, after the cells had been removed by centrifugation, adsorbed GRF was tested for their helper-cell inducing capacity: T cells purified on nylon wool were used. Figure 1 shows that GRF is adsorbed by spleen cells after passage through nylon wool (containing about 1% B cells) as well as by anti-θ serum and complement-treated spleen cells (not shown), but not by macrophages. The latter point is important, making it unlikely that GRF is not synthesised by macrophages. The adsorption by anti-θ-treated spleen cells could be due to (1) residual T cells, (2) dead, but not lysed, T cells or (3) B cells. Indeed, anti-θ-treated spleen cells from which the dead cells were removed before adsorption could not adsorb out GRF activity (for example, see legend to Fig. 1). This indicates that dead cells can remove GRF, presumably because their receptors are still intact. The adsorption by T cells seems to be specific and may be related to the mechanism of GRF, action, for it is dependent on the number of T cells used for adsorption (data not shown), and because T cells incubated with GRF for 1 h at room temperature, then washed thoroughly, and cultured for 4 d were stimulated to become helper cells without further contact with GRF, macrophages or antigen (Fig. 3).

The genetics of adsorption of GRF was investigated. Allogeneic (C57BL/10=B10, H-2^b) spleen or thymus cells did not adsorb CBA GRF at a ratio of 10^8 cells per ml of GRF in contrast to syngeneic spleen cells or thymocytes (Fig. 2). Even 2 × 10^9 allogeneic cells were insufficient. To pursue the genetics of GRF adsorption further, GRF obtained from either CBA, B10.A(4R), AQR, B10 or B10.A(5R) macrophages were first adsorbed with spleen

Table 2 Genetics of the GRF-receptor on spleen cells

GRF (1ml) obtained from macrophages of various mouse strains were incubated with either A.QR, CBA, B10.A(4R) or B10 spleen cells for 1h at room temperature. The adsorbed GRF were then tested on their helper-cell-inducing capacity by incubating with either nylon wool-purified B10.BR or B10 T cells for 4 d as described in the legend to Table 1. For each combination, the H-2 subregion (of the k or b haplotype) is listed which is shared by GRF and the spleen cells used for adsorption, and in which they differ, within the left half of the H-2 complex. For example, AQR spleen cells and B10.A(4R) GRF share the I-A^k subregion but differ for the K^k subregion (lines 8 and 9). Thus the diminished activity of the B10.A(4R) GRF after adsorption with A.QR spleen cells indicates that the latter contain GRF receptors on their surface which are coded for by genes of the I-A^k and not of the K^k subregion. Five experiments of this type have been performed, for three of them nylon wool-purified T cells were used for adsorption instead of spleen cells, and other combinations were also tested with analogous results. The controls were:

B10.BR spleen cells	+ TNP-KLH (0.1 μg ml^{-1})	33 ±	27
	+ DNP–beads 3%	3030 ±	965
B10 spleen cells	+ TNP-KLH	107 ±	12
	+ DNP–beads 3%	4470 ± 1078	

Other subdivisions of the H-2I region have been described —I-E and I-J (personal communication from C. S. David and D. B. Murphy). But because these are all to the right of I-B, they do not affect the mapping studies described here.
Fig. 2 Evidence for genetic control of the GRF receptor. CBA GRF$_{KLH}$ (a) or B10 GRF$_{KLH}$ (b) (1 ml) were adsorbed with either 1×10^8 CBA or B10 spleen cells (spl) or thymocytes (thy) for 1 h at room temperature. After removal of the cells by centrifugation the adsorbed GRF was tested on their helper-cell-inducing capacity by incubation with 15×10^6 nylon wool-purified CBA (a) or B10 T cells (b) in a concentration of 10% as described in the legend to Table 1. Other concentrations of GRF have also been tested, but for convenience only one concentration is shown here. As controls, unadsorbed GRF or no GRF were used. The dotted line represents the background as described in the legend to Fig. 1. Seven experiments of this type have been performed with analogous results.

cells from AQR, CBA, B10.A(4R) or B10 mice (10^6 cells per ml of GRF) and then tested for their helper-cell inducing capacity with B10.BR and B10 T cells. Table 2 shows that the adsorption of GRF by T cells is also determined by gene(s) of the *H–2* complex, located in the I-A subregion. The simplest interpretation for these results is that the receptor for GRF (which initiates the helper pathway) is controlled by genes in the I-A subregion. These results, however, do not exclude the possibility that the bulk adsorption measured here could be due to a different type of binding unrelated to the manner by which GRF stimulates helper cells. This possibility can be excluded by testing the adsorption of GRF functionally, that is whether adsorbing T cells of different strains were stimulated. Preliminary experiments with B10.A(4R) and AQR mouse strains which are identical only at the I-A$_k$ subregion of the MHC have shown that B10.A(4R) T cells are stimulated by AQR GRF. Together with the other data, this indicates that the T-cell receptor for GRF is involved in the activation of these cells, and that this T-cell receptor is controlled by the I region of the MHC.

Taken together the results indicate that at least two genes, each located in the I-A subregion, but expressed on different cells, regulate helper-cell induction. One gene codes for the Ia part of GRF, the other for the GRF receptor.

It is not likely that macrophages and T cells express both of the genes under consideration, because if so macrophages would adsorb GRF, which they do not (Fig. 1), and T cells would make GRF, which they also do not.

The possibility that the receptor for GRF, since it is controlled by the I region is an Ia antigen was tested by attempting to inhibit the adsorption of GRF by prior treatment of the T cells (which carry these receptors) with anti-Ia sera. A.TH anti-A.TL antisera, with cytotoxic titres of 1/5,000 to 1/1,000 (on spleen) and functional titres of 1/100 or more (on suppressor T cells) did not inhibit binding of GRF to the receptor, even at concentrations of 1/3, whereas the same antisera (at concentrations of 1/3, 1/30 and even of 1/1,000 in other experiments) bound GRF, if incubated together and inhibited its helper-cell-inducing capacity (Fig. 3). These results suggest that the receptor for GRF is not a classical Ia antigen.

It has been shown that the immune response to some antigens is controlled by two genes located in the *H–2* complex. Munro and Taussig[17] postulated a two-gene model for the response to the branched synthetic polypeptide (T,G)–A—L, both mapping in the I-A subregion of the *H–2* complex, with one of these genes expressed in T cells, the other in B cells. The immune response to the terpolymer L-Glu, L-Lys, L-Phe (GLØ) has also been shown to be controlled by two complementary genes in the *H–2* complex, one of which was mapped in the I-A subregion, the other somewhere to the right of the I-C subregion[18,19]. These reports deal with antigens which are clearly under immune response (*Ir*) gene control, whereas our study was performed with an antigen not known to be under *Ir* gene control. Shevach *et al.*[24] have shown in the guinea pig, however, that antisera directed against the guinea pig equivalent of the I region (for example, strain 2 anti-strain-13 sera), only inhibit responses in F$_1$ (2×13) animals controlled by the relevant I region, for example, the prolifera-
Fig. 3 The GRF receptor on T cells is not Ia antigen. 15×10^6 nylon wool-purified CBA T cells (T) were first incubated with anti-Ia serum (A.TH anti-A.TL batch no. 383) diluted 1:3, 1:30 and 1:3,000 for 3 or 4 h at room temperature. After washing, cells were incubated with CBA GRF$_{KLH}$ (0.1 ml per 15×10^6 cells) for 1 h at room temperature. After repeated washings, the T cells were incubated in Marbrook flasks for 4 d to facilitate helper-cell induction (Tads.aIa, ads. GRF). Simultaneously 15×10^6 T cells, GRF (10%) and anti-Ia^k serum in the same dilutions were incubated together for 4 d (T+aIa^k+GRF). As controls, T cells were incubated without GRF (nil), with GRF (T+GRF) or after adsorption with GRF (Tads.GRF). The procedure to measure helper activity is described in the legend to Table 1. The dotted lines represented background levels (spleen cells incubated without antigen (nil) or with TNP-KLH (TK) but without helper cells). Four experiments of this type have been performed with analogous results.

tion response to the synthetic polypeptide GT (a polymer of glutamic acid and tyrosine), an antigen the response to which is controlled by a 13-linked *Ir* gene, was inhibited by anti-13 sera. Schwartz *et al.*[25] have obtained similar results in the mouse which imply a functional relationship between *Ir* gene products and Ia antigens. Thus it is possible, even likely, that the reaction described here is a component of the function of H-2-linked *Ir* genes. At present the number of genes influencing helper-cell induction is not known, but results presented here and elsewhere indicate that at least two I region genes are involved.

The most interesting question raised by this study—the mechanism by which GRF is recognised by T cells—is still not resolved. Do helper precursor T cells have two receptors for GRF, one for the Ia product and the other for the antigen, or is there one receptor for "modified Ia" as suggested by Miller's studies[26] in delayed type hypersensitivity and in analogy to the modified H-2 involved in the killing of virus-infected cells[27] or of hapten labelled cells[28]. Our analysis does not permit an answer, but studies are in progress to resolve this issue.

We thank Dr Chella David for (A.BYxB10.HTT)F₁ anti-A.TL and (B10(4R)×129)F₁ anti-B10.A(2R) sera, Dr I. McKenzie for A.TL anti-A.TH, Dr D. Sachs for A.TL anti-A.AL serum and B10.A(4R) anti-B10.A(2R) sera, Dr D. Parker for DNP–polyacrylamide beads and Dr E. Simpson for congenic strains of mice. This investigation was supported by a grant from the Swiss National Foundation and by the Imperial Cancer Research Fund.

Liposome-induced morphological differentiation of murine neuroblastoma

LIQUID crystals made of lipids (liposomes), initially devised as models of biological membranes[1–4], have more recently

been used as artificial carriers because of their ability to bind and fuse with biological membranes and discharge their soluble content into the cytoplasm[5–7]. Preliminary studies in our laboratory have shown that lisopsomes loaded with the nerve growth factor (NGF) induce morphological differentiation in a murine neuroblastoma cell line which does not exhibit morphological changes on addition of NGF to the culture medium. Control experiments with liposomes in absence of NGF however, also resulted in process formation in neuroblastoma (NB) cells. Our attention was therefore focused on the effect of the carrier itself, rather than on the agent carried.

A neuroblastoma cell clone (NB41A₃) was obtained from Dr Augusti-Tocco[8] and maintained in suspension in F10 medium (Gibco), supplemented with 15% horse serum and 2.5% foetal calf serum (EUROBIO, Paris), penicillin G (200 U ml⁻¹), and streptomycin sulphate (200 μg ml⁻¹) in an humidified incubator conditioned with 5% CO₂ and 95% air, at 37 °C. Egg yolk phosphatidyl choline (PC), phosphatidyl serine (PS), phosphatidyl ethanolamine (PE), phosphatidic acid (PA) and sphingomyelin (SM) were purchased from Lipid Products, South Nutfield, Surrey. N⁶,O²-dibutyryl cyclic AMP, 5-bromodeoxyuridine (BUdR) and papaverine were obtained from Sigma, dimethylsulphoxide (DMSO) was from Merck.

The first set of experiments was directed to find the optimum conditions (liposome composition, time of incubation, temperature) for maximum binding. This process was measured by the amount of ¹⁴C–PC mixed with the phospholipids forming the liposomes, which was not removed by three consecutive washings of the cells after incubation. This measure of 'tightly bound' liposomes does not, however, indicate whether binding is followed by fusion and/or interiorisation within the cell cytoplasm. These experiments indicated that a mixture of sonicated PC–PS 10 : 1.5 (w/w) liposomes progressively attached to, and/or penetrated the cell membrane during a 24-h incubation period at 37 °C. At the end of this time, 0.2–0.4% of the total liposomes present in culture was tightly bound to the cells. Addition of cholesterol to this lipid suspension did not significantly change the pattern of binding. Changing the net charge of the liposome from negative to positive by introducing stearylamine severely reduced the viability of NB cells.

The marked morphological changes (process formation) induced by liposomes are shown in Fig. 1*a* and *b*, which compares cultures of the same NB cell line in the absence or presence of this lipid suspension. The fine structure of the liposome-induced processes (Fig. 1*c*) shows an abundance of microtubules (MT) lying in parallel arrays. In addition to MTs, other fibrillar structures tentatively identified as microfilaments (MF) are also seen in most liposome-treated cultures. The number of cells present in cultures containing liposomes is 40% lower after 24 h and 60% lower after 48 h, than in control cultures. During the same period, the TCA precipitable ³H-methylthymidine is reduced to 30% of controls when expressed as counts per mg of total protein. These findings suggest that liposome-induced morphological differentiation is accompanied by a concomitant inhibition of cell division, although we cannot yet decide whether the two phenomena are correlated or independent. Autoradiographic studies show heavily labelled NB cells following incubation with ¹⁴C liposomes for after only 3 h of incubation (Fig. 2). Whether the radioactivity is confined to the cell surface, or whether it is also within the cytoplasm, is not known.

Several substances have been shown to induce morphological or biochemical maturation of NB cells[9–13]. In our NB system, however, only dibutyryl cyclic AMP induced process formation, although not to the same extent as liposomes: other agents such as papaverine, 5-bromodeoxyuridine and dimethylsulphoxide, had little or no effect. It is worth mentioning that PS liposomes injected *in vivo*,
Fig. 1 Effect of liposomes on the morphology of neuroblastoma cells. NB cells (NB41A$_3$) were plated in a Falcon dish containing coverslips. After 3 h, 100 μl (2.7 mg of total phospholipids) of the suspension of liposomes was added to a series of cultures (*b*, *c*) or the same volume of Gey's balanced salt solution was added to control cultures (*a*). After 3 d, the cultures were fixed either for light microscope observation (*a*, *b*) or for electron microscopic studies (*c*). *a*, *b*, Microphotographs taken using phase contrast were fixed with Dubosc Brasil and stained with haematoxylin. *c*, Electron micrography of a portion of neurite from the same culture as shown in (*b*). Cells were fixed in 3% glutaraldehyde in 0.1 M phosphate buffer with Ca^{2+} added in the same buffer and post-fixed in 1% OsO$_4$, dehydrated and embedded in Epon 812. Photo was taken with Philips E.M. 300. Magnifications: *a* and *b*, ×174; *c* ×2,079. Liposomes were prepared as described previously[1-3]. Generally, 20 mg lecithin from egg yolk was mixed with 3.0 mg phosphatidylserine in 1.0 ml of chloroform–methanol 2:1 (v/v) and dried under a vacuum pump. Gey's balanced salt solution (1 ml) was added and stirred vigorously for 5 min in a vortex mixer. Sonication was in a constant flow of nitrogen gas for 25 min. Liposomes obtained in this way are round, with a diameter of about 120–200 Å measured after ammonium molybdate staining, in the electron microscope.

have been shown to increase brain glucose and decrease catecholamine content of the adrenal medulla[14,15].

Our findings raise the question as to the mechanism by which pure lipids, which are normal constituents of the cell membrane, can induce morphological maturation of a neoplastic cell line. Using ^{14}C–PC-loaded liposomes incubated at a concentration of 1.0 μmol^{-1} with 4×10^6 cells, we have found that 2–4 nmol of liposomes are bound to, or have penetrated, the cells. This value corresponds to an average of 3×10^8 phospholipid molecules per neuroblastoma cell, that is, (assuming that a sonicated liposome is formed by 2×10^3 phospholipid molecules[2]), 1.5×10^5 liposomes bound per cell. A liposome bound to the membrane of a living cell may undergo endocytosis, or it may fuse with the membrane itself and become part of its constituents. If the fate of phospholipids is mainly to become constitutent parts of the cytoplasmic membrane, their contribution to the

Fig. 2 Autoradiograph of NB41A$_3$ treated with radioactive liposomes. PC-PS liposomes were prepared as described in Fig. 1 in the presence of 1 μCi ml^{-1} ^{14}C–PC (New England Nuclear, specific activity 1.765 Ci mmol^{-1} P). After incubation for 3 h, cells (which were grown on coverslips in a Falcon dish) were fixed in 3% glutaraldehyde in 0.1 M phosphate buffer *p*H 7.2. After 1 h in fixative, cultures were washed in the same buffer, and stained in haematoxylin. The coverslips were air dried and coated with Ilford L4 emulsion. After 50 d of exposure at room temperature, the autoradiograms were developed with Microdol at 21 °C for 6 min. Microphotographs were taken with: *a*, transmission light; *b*, interference differential (Zeiss–Nomarski) microscope. Magnifications for *a* and *b* ×824.
entire surface of each NB cell of diameter 15 μm could be between 5 and 20%, a not insignificant increase for the functional properties of a membrane. Considering that PS molecules are negatively charged and exhibit particular binding capacity for Ca^{2+} and monovalent cations, changes in the net charge of the membrane can be expected following binding and/or fusion of the phospholipids forming the liposomes. The considerable amount of bound phospholipids might also influence the permeability of these cells and effect the organisation of the fibrillar proteins (microtubules, microfilaments) which are essential in axonal growth and elongation.

It remains to be ascertained to what extent *in vitro* process formation in NB cells is a true morphological sign of neural differentiation, since this effect can be induced not only by specific substances[10-13] but also by noxious agents or treatments[11,12]. The use of liposomes may contribute to this controversial problem, since their action seems to involve a mechanism which is not dependent on a specific signal, nor do they cause a detrimental effect on the responsive system.

We thank Dr R. Levi-Montalcini for discussions during the preparation of the manuscript and Dr Augusti-Tocco for supply of NB41A3 cells.

Reduction of sexual interaction in rhesus monkeys by a vaginal action of progesterone

PROGESTERONE acting in the female seems to reduce sexual interaction in several primate species. It has been reported that sexual activity declines during the luteal phase of the menstrual cycle (when circulating progesterone levels are maximal), in monkeys[1-3], lowland gorillas[4] and humans[5], and that administering progesterone to ovariectomised, oestrogen-treated rhesus monkeys has a similar effect[6]. A major unresolved question is how progesterone causes these changes in behaviour. One possibility is that progesterone acts on the female's central nervous system, causing her to accept or solicit fewer male mounts. Another is that progesterone somehow alters the vagina thereby changing non-behavioural cues (such as a smell[7] or tactile qualities) which contribute to her sexual attractiveness. Here we present evidence favouring the second mechanism, since the

reduction in sexual interaction caused by systemic administration of a physiological dose of progesterone to female monkeys could be reproduced by instilling very small amounts of this hormone directly into the vagina.

Ovariectomised female and intact male adult rhesus monkeys (*M. mulatta*) were used. The females were implanted subcutaneously with silastic tubing (Dow Corning, 4 cm long, 3.35 mm inner and 4.65 mm outer diameters) filled with oestradiol-17β, which results in plasma levels of oestradiol similar to those measured in the follicular phase of the menstrual cycle[8]. Animals were housed separately between observations. Sexual interaction between heterosexual pairs of monkeys selected because they copulated readily without displaying aggression was studied from behind a one-way mirror[9]. In each experiment the same pairs were tested daily in a constant order until the male ejaculated, or for a maximum of 30 min. Here we consider only the following behavioural measures: (1) for the male, mounting rate (number of mounts per min) and the percentage of tests with ejaculation; and (2) for the female, acceptance ratio (the percentage of male mounting attempts accepted) and the number of sexual invitations[10] offered to the male per observation. Plasma progesterone was estimated by radioimmunoassay, using at least two dilutions of plasma[11].

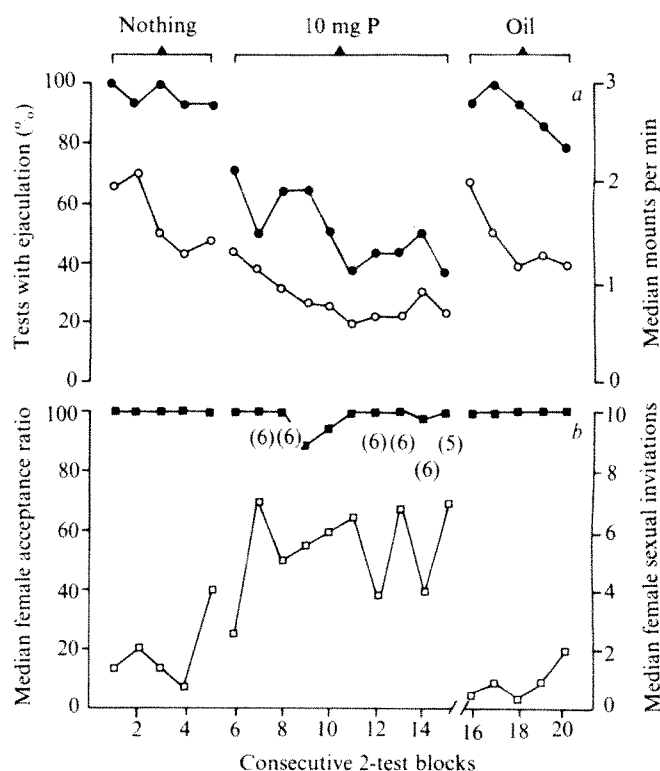
In experiment 1 six females were given daily intramuscular injections of 10 mg progesterone in arachis oil, which after 20 d resulted in plasma levels of progesterone (median: 10.74 ng ml⁻¹, range: 5.16–14.52) within the


Fig. 1 Effect of 10 mg d⁻¹ progesterone given intramuscularly to the female on sexual interaction in pairs of rhesus monkeys (experiment 1). Five females were tested with one of three males, and another female with two different males. An interval of 32 d, during which no treatment or tests were administered, intervened between test blocks 15 and 16. Two parameters of the males' sexual behaviour are shown in *a*: ●, % tests with ejaculation; ○, median mounts min⁻¹; and two of the females' in *b*: ■, median acceptance ratio; □, median sexual invitations. Data points are based on seven pairs. Exceptions, which are indicated in parentheses, represent tests in which no acceptance ratio could be calculated for some pairs. The statistical comparisons were made with the initial control condition using 2-tailed Wilcoxon tests, provided an initial Friedman analysis of variance was significant ($P < 0.05$).
Fig. 2 Effect of low doses of progesterone intravaginally on sexual interaction (experiment 2). Six females were tested with one of six males, and another female with two different males. After each day's behavioural testing, arachis oil solutions were administered by inserting a catheter adaptor attached to a 1–ml syringe into the vagina until it touched the cervix, when it was withdrawn slightly and the injection made. Data points are based on eight pairs, exceptions being indicated in parentheses. Behavioural parameters (*a*, male; *b*, female), statistical analysis and symbols as in Fig. 1.

range measured during the luteal phase of the menstrual cycle[8]. This treatment caused significant reductions in the males mounting rate and ejaculation ($P<0.02$), whereas the females continued to accept virtually all the mounting attempts and actually displayed a threefold increase in sexual invitations ($P<0.02$) (Fig. 1). Thus, physiological increases in circulating progesterone made the females significantly less attractive to male partners, without altering neural mechanisms so as to depress receptivity. Our results contrast with the reported[6] reduction in receptivity in some female monkeys which occurred following administration of a pharmacological dose of progesterone (25 mg d^{-1}). In a second experiment, we investigated the possibility that

Table 1 Plasma progesterone in seven ovariectomised, oestradiol-treated female rhesus monkeys following intravaginal and intra-muscular administration of progesterone

Site and amount of progesterone administered in 0.1 ml arachis oil	Treatment duration (d)	Plasma progesterone (ng–ml) (Median)	(Range)
A Vagina			
0	10	0.12	<0.10–0.41
250 µg	10	0.29	<0.10–0.43
1,000 µg	10	0.30*	0.15–0.52
0	14	0.15	<0.10–0.24
B Thigh muscle			
0	10	0.20	<0.10–0.51
250 µg	10	0.59*	0.28–0.83
1,000 µg	10	0.81†	0.63–1.32

Within each experiment, comparisons were made with the initial 0 condition using one-tailed Wilcoxon tests. Blood samples were collected 24 h after the last injection in each treatment block. *$P<0.05$, †$P<0.01$.

progesterone affected sexual interaction by acting directly on the vagina.

In experiment 2, instilling progesterone directly into the vagina duplicated the behavioural effects obtained with systemic administration in experiment 1. Figure 2 shows that giving 250 µg d^{-1} progesterone intravaginally caused a significant decline in mounting rate and a significant increase in sexual invitations by the females ($P<0.02$). The incidence of ejaculation declined when the dose of progesterone was raised to 1,000 µg d^{-1}; however, masculine sexual performance returned to initial control levels after intravaginal progesterone treatment was stopped. Females' acceptance ratios remained high throughout the experiment. Intravaginal administration of 250 µg progesterone had no significant effect on plasma levels, although treatment with 1,000 µg caused a slight, though significant increase (Table 1*A*). These findings suggest that progesterone altered sexual interaction primarily by acting on the vagina. The increased display of sexual invitations by females which was observed did not, therefore, result from the direct action of progesterone on neural tissues controlling this behaviour. Instead, it may reflect an attempt by females to compensate behaviourally for a progesterone-induced reduction in sexual attractiveness.

Fig. 3 Effect of low doses of progesterone intramuscularly on sexual interaction (experiment 3). Six females were tested with one of five males. Data points are based on six pairs, exceptions being indicted in parentheses. Behavioural parameters (*a*, male; *b*, female), statistical analysis and symbols as in Fig. 1.

These conclusions were supported by the results of experiment 3, in which the same low doses of progesterone were administered intramuscularly instead of intravaginally. Plasma levels of progesterone increased significantly when 250 µg d^{-1} progesterone was given intramuscularly (Table 1*B*); however, this treatment had no significant effect on sexual interaction (Fig. 3). Giving 1,000 µg progesterone raised plasma progesterone levels even more and caused a significant decline in males' mounting rate and ejaculation ($P<0.05$). The females' receptive behaviour was not affected, although in this experiment the increase in their sexual invitations induced by progesterone was not significant. The fact that progesterone in the lower dosage had to be instilled directly into the vagina (experiment 2) to

affect sexual interaction demonstrates that the behavioural effects of this steroid result from its action in this tissue.

Oestradiol enhances sexual attractiveness of female monkeys by affecting the vagina[11]. It may act by stimulating the emission of olfactory attractant cues[7] or by altering the tactile qualities of this tissue. Progesterone could reduce the sexual attractiveness of the females by blocking these effects of oestradiol in the vagina. A comparable anti-oestrogenic action of progesterone has been demonstrated in the oviducts of rhesus monkeys[11]. Alternatively, progesterone could act synergistically with oestradiol to stimulate the production of a vaginal olfactory cue which actively reduces female sexual attractiveness. Either mechanism could account for the reduction in sexual attractiveness which has been reported in different primate species[14] (including humans[9]) at times when the female's plasma progesterone levels are elevated.

Hypertensive effect of 17α, 20α-dihydroxyprogesterone and 17α-hydroxyprogesterone in the sheep

ANIMAL experimental models of high blood pressure as caused, for example, by renal artery constriction or administration of mineralocorticoid hormones and salt, have yielded basic data on physiological processes which have helped in the diagnosis and treatment of human hypertension. The discovery that ACTH administration causes a reproducible hypertension of rapid onset in the sheep provided a new model for analysis[1,2]. Certain clinical observations have indicated that there may be as yet unidentified steroids which are causally involved in some hypertensive states: for example, instances of high blood pressure in children and adults which were corrected by dexamethasone treatment[3,4], and reversal of high blood pressure in the low renin group of essential hypertensives by inhibitors of steroidogenesis or by spironolactone have been described[4-6]. We report here the hypertensive effect of 17α, 20α-dihydroxyprogesterone

(17α,20α-diOHP; 17α,20α-dihydroxy-4-pregnene-3-one) and 17α-hydroxyprogesterone (17α-OHP) in sheep made hypertensive with ACTH. These two progesterones were identified in the adrenal venous effluent from ACTH-hypertensive sheep and were shown to be secreted in greatly increased amounts.

Animal experimental procedures have been described in detail previously[1,2]. The animals were habituated over several weeks of training to blood pressure measurement by the same observers, and the daily mean was based on 6–8 readings during morning and afternoon. In the absence of a recognisable disturbance in the laboratory, variation in the trained animal during the day was small—less than 5 mmHg. After a control 3–5-d period, intravenous steroid infusions were carried out over 5 d using the same measurement protocol as in the ACTH and the other steroid infusion experiments[1,2].

ACTH administration (80 IU d^{-1}) to the intact, but not the adrenalectomised sheep, results in a significant elevation of arterial blood pressure within 24 h and this is sustained over 5–10 d of ACTH treatment[1] (Fig. 1, group e). Hypokalaemia, an increase in plasma sodium, and increased water intake and urine output were also observed[1]. Changes in blood pressure were not related to changes in external body Na status or in body weight. Intravenous infusion of cortisol, corticosterone, deoxycorticosterone (DOC), aldosterone and 11-deoxycortisol either singly, or in combination at rates to give blood levels similar to those found during ACTH administration (cortisol, 5 mg h^{-1}; corticosterone, 0.5 mg h^{-1}; 11-deoxycortisol, 1 mg h^{-1}; DOC, 25 μg h^{-1}; aldosterone, 3 μg h^{-1}), failed to reproduce the elevation in blood pressure[2] (Fig. 1, group a). The combined steroid infusion, however, did reproduce all other metabolic responses seen in the ACTH experiments[1,2]. In addition, the combined steroids together with 18-hydroxydeoxycorticosterone (18-OHDOC, 100 μg h^{-1}) did increase blood pressure on the fifth day[2] (Fig. 1, group b). This has been confirmed in an additional six experiments.
Fig. 1 Mean systolic and diastolic blood pressure (±s.e.m.) before (pre) and after 1 and 5 d of the combined steroid infusion (group a); combined steroid plus 18-OHDOC (group b); combined steroid plus 17α-OHP (group c); combined steroid plus 17α,20α-diOHP (group d), and ACTH (group e). Statistical comparisons with control (pre) observations have been made using Students' t test for paired observations. *P < 0.05; **P < 0.01; †P < 0.005.

The animals in the first group (n = 5) were given the combined steroid infusion together with 17α-OHP (Steraloids Inc.) at a rate of 1 mg h^{-1} for 5 d. This rate approximated the rate of adrenal secretion of the hormone measured during ACTH-induced hypertension in conscious trained sheep with an adrenal transplant[7], or with an adrenal-jugular bypass operation[8]. The administration rate was thus in the physiological range of adrenal functional capacity to secrete the hormone. Systolic blood pressure increased from 82 ± 1 (mean ± s.e.) to 94 ± 2 and 102 ± 2 mmHg on the fourth (P < 0.05) and fifth day (P < 0.005), respectively (Fig. 1, group d). Diastolic blood pressure showed a significant increase 56 ± 1–61 ± 1 mmHg on

the second day ($P < 0.005$). Neither systolic nor diastolic blood pressure was elevated within the first 24 h.

Animals in the second group ($n = 6$) were given a combined steroid infusion together with 17α,20α-diOHP (Steraloids Inc.) at 500 μg h^{-1}. As in the first group, this rate approximated the physiological output determined during ACTH-induced hypertension and both systolic and diastolyic blood pressure were raised significantly within 24 h. Systolic pressure rose from a control of 85 ± 2 to 92 ± 3 mmHg ($P < 0.01$) (Fig. 1, group c); on the final day of infusion, it was 100 ± 3 mmHg ($P < 0.01$). Diastolic blood pressure rose from a control of 60 ± 3 to 68 ± 3 mmHg ($P < 0.01$) and was significantly elevated at 70 ± 2 mmHg on the fifth infusion day ($P < 0.005$).

Preliminary experiments in two animals indicated that neither 17α-OHP nor 17α, 20α-diOHP, when infused alone at the same rate as described above, caused any increase in blood pressure over a 5-d period. In a further two experiments where they were given together with the combined steroid infusion, the blood pressure response was similar to that seen in the second group of experiments.

In the study with combined steroid plus 17α,20α-diOHP, urinary sodium response involved a rather more sustained initial sodium retention than with ACTH, although blood pressure effects were similar. All other metabolic responses were similar to those in response to ACTH. The more sustained urinary Na retention occurred both with 17α-OHP with combined steroid, and when 17α,20α-diOHP and 17α-OHP were infused together with the combined steroid mixture. When either of these steroids was infused alone, without the concurrent combined steroid infusion, they were without effect on urinary sodium excretion.

There is, however, evidence that urinary sodium retention is not the primary mechanism of ACTH hypertension. Sodium depletion of 15–20% of the exchangeable sodium pool by acute parotid duct cannulation before the start of 5 d of ACTH treatment, reduced urinary Na excretion to basal levels. In six animals this did not alter the time course of the blood pressure response to ACTH[9]. Sodium depletion was also carried out in seven animals after the 5-d ACTH treatment, with ACTH being continued over a further 2 d. The blood pressure, though reduced by depletion was still significantly elevated at the end of the sodium depletion period[9]. In five experiments where ACTH was given 24 h after bilateral nephrectomy, there was no difference in blood pressure response from that of intact animals. Although these data support the theory that urinary sodium retention is not the cause of the ACTH hypertension, we cannot formally exclude the possibility that it may be influential in the hypertensive effect of 17α-OHP and 17α,20α-diOHP plus combined steroid infusions.

Hypertension associated with excessive endogenous steroid production or administration of exogenous steroids, has been widely reported clinically and in experimental studies. Whereas the cause of increased blood pressure in some of these studies is well known, with others, the cause(s) are not clear. Historically, two classes of steroids—mineralocorticoids such as aldosterone, DOC and corticosterone, and glucocorticoids such as cortisol and 11-deoxycortisol—have been believed to be able to cause hypertension. The exact mechanism by which these types of hypertension are produced and the precise relationship between these steroids, sodium status and blood pressure are still largely undefined. Other naturally occurring steroids—for example, 18-OHDOC and 16-βOH-dehydroepiandrosterone—have been investigated for their hypertensive activities[4,10]; the former increases blood pressure in the dog[11] and sheep[2] but any hypertensive action of the latter requires confirmation. In the present study, two steroids previously unrecognised as having an hypertensive action were shown to increase blood pressure in sheep when given at high physiological dosages concurrent with, and conditional on, elevated levels of a number of other adrenocortical hormones.

The mechanism by which these two steroids influence blood

pressure is not yet clear. The fact that alone, they do not increase blood pressure, nor do they reduce the salivary Na–K ratio following ipsilateral carotid artery infusion in the Na-deficient adrenalectomised sheep, suggests they are not classical mineralocorticoids. Because doubling the cortisol component of the combined steroid infusion does not reproduce the blood pressure increase of ACTH or addition of 17α,20α-diOHP, it is unlikely that they simply add to an existing glucocorticoid-type effect. If they are not glucocorticoids, then recognition of a class of steroids which can increase blood pressure, but which may not act as classical mineralocorticoids, could have important implications for future clinical research and experimental models of hypertension.

Mode of action of endogenous opiate peptides

AS THE culmination of a search for endogenous ligands of the opiate receptor[1-4], the structures of two closely related pentapeptides, isolated from porcine brain, with morphine-like properties in pharmacological tests, have been reported by Hughes *et al*[5]. The amino acid sequences of the pentapeptides, termed methionine enkephalin and leucine enkephalin, are Tyr-Gly-Gly-Phe-Met (Met^5-enkephalin) and Tyr-Gly-Gly-Phe-Leu (Leu^5-enkephalin), respectively. They behave as highly potent opiates in the mouse vas deferens and guinea pig ileum assays[5]. In addition, animals tolerant to morphine are also tolerant to enkephalin[6]. The action of the pentapeptides in the guinea pig ileum[5] and when injected intracerebrally or intracerebroventricularly[7-9] is very short lived, perhaps because of proteolytic degradation. A related peptide, with longer chain length has been shown to have a long duration of action[10]. Morphine and other narcotics have been shown to bind to the opiate receptor[11-13] and inhibit adenylate cyclase activity in homogenates of neuroblastoma × glioma hybrid cells[14,15], to inhibit cyclic AMP accumulation in intact hybrid cells[15,16] and in rat brain homogenates[17]. We have tested the effects of Met^5- and Leu^5-enkephalin on NG108-15 adenylate cyclase activity, and show here that endogenous opiate peptides are potent, receptor-mediated, inhibitors of adenylate cyclase of neuroblastoma × glioma hybrid cells.

NG108-15 hybrid cells were derived (unpublished results of B. Hamprecht, T. Amano and M.N.) by fusion of mouse neuroblastoma clone N18TG-2[18] with rat glioma clone

C6BU-1[19]. NG108-15 cells generate action potentials on electrical or chemical stimulation, synthesise acetylcholine (unpublished results of B. Hamprecht, T. Amano and M.N.), and form synapses with striated muscle cells[20]. They are richly endowed with opiate receptors[14].

The relationship between Met[5]-enkephalin, Leu[5]-enkephalin, and morphine concentrations and basal or prostaglandin E₁ (PGE₁)-stimulated NG108-15 adenylate cyclase activities are shown in Fig. 1a and b, respectively. The concentrations required for half-maximal inhibition of basal adenylate cyclase are 12, 40 and 1,500 nM, respectively, and 20, 120 and 1,500 nM for PGE₁-stimulated activity. Therefore, Met[5]-enkephalin and Leu[5]-enkephalin are approximately 100 and 25 times more potent than morphine as inhibitors of adenylate cyclase activity. The activities of Met[5]- and Leu[5]-enkephalin as inhibitors of adenylate cyclase are approximately equal to their activities as inhibitors of electrically evoked contractions of mouse vas deferens smooth muscle and are five times greater than their activities in a similar assay with guinea pig ileum[6].
Fig. 1 Basal and PGE₁-stimulated adenylate cyclase activity of NG108-15 homogenates as a function of concentration of Met[5]-enkephalin (□), Leu[5]-enkephalin (○) or morphine (△). Reaction mixtures were incubated for 5 min at 37 °C with 97 μg of homogenate protein per tube. Other conditions are described in Table 1. Met[5]-enkephalin was synthesised by the rapid solid-phase procedure of Corley et al.[21] The peptide product (approximately 80% pure) was purified by high-pressure liquid chromatography using a reversed phase system (Corasil, Waters Associates) and an acetonitrile, 0.1-M acetic acid gradient Leu[5]-enkephalin, a synthetic product, was the gift of Drs R Simantov and S. H. Snyder.

The effectiveness of Met[5]-enkephalin (1.6 × 10⁻⁷ M) as an inhibitor of adenylate cyclase decreases during incubation (Fig. 2), and is lost after approximately 20 min. The degree of inhibition by morphine (2 × 10⁻⁷ M) also decreases during incubation, but to a lesser extent. Further work is needed to determine whether Met[5]-enkephalin and morphine are inactivated during incubation or whether an activator of adenylate cyclase is formed.

The effect of naloxone, an opiate antagonist which competitively inhibits narcotic binding to the opiate receptor, on Met[5]-enkephalin or morphine-dependent inhibitions of adenylate cyclase are shown in Fig. 3a and b, respectively. Different concentrations of naloxone were used in the presence of 10⁻⁸, 10⁻⁷ or 10⁻⁶ M Met[5]-enkephalin or in its absence. Naloxone completely reverses the inhibition of adenylate cyclase by each concentration of Met[5]-enkephalin tested. As expected for competitive interactions at a single

Table 1 Effect of Met[5]-enkephalin and morphine on adenylate cyclase activity in homogenates of neuroblastoma × glioma hybrid and parental cell lines

	Cell line		
	Hybrid	Neuroblastoma	Glioma
Additions	NG108-15	N18TG-2	C6BU-1
	pmol cyclic AMP per min per mg protein		
None	41.4	13.2	15.8
Met[5]-enkephalin	27.2	14.7	15.1
Morphine	35.9	16.8	16.8
PGE₁	217	115	20.5
PGE₁ + Met[5]-enkephalin	168	120	18.4
PGE₁ + morphine	164	121	20 2

Adenylate cyclase activity was measured by the procedure of Salomon et al.[13] with modifications described before[14]. Each reaction mixture contained, in a final volume of 100 μl: 30 mM Tris-HCl, pH 7.5, 5 mM MgCl₂; 160 mM sucrose; 20 mM creatine phosphate; 10 U of creatine kinase; 1 mM ³H-cyclic AMP (10,000 c.p.m.), 0.5 mM RO20-1724 (0.1% ethanol final concentration); 1 mM α-³²P-ATP (10⁶ c.p m.); and where indicated, 0.16 μM Met[5]-enkephalin; 20 μM morphine sulphate; and 10 μM PGE₁. In addition, 90, 95 and 118 μg of homogenate protein was present for NG108-15, N18TG-2 and C6BU-1, respectively. Tubes were incubated for 3 min at 37 °C. Reactions were stopped with 1 ml of 5% trichloroacetic acid containing 1 mM ATP and 1 mM cyclic AMP. ³²P-cyclic AMP and ¹⁴C-cyclic AMP (for recovery) were counted after purification as described by Salomon et al.[13]. Cell lines, growth conditions and the adenylate cyclase assay method have been described previously (refs 14 and 15 and unpublished results of B. Hamprecht, T. Amans and M. N.). Washed cells, suspended in 0.32 M sucrose, 0.01 M Tris-HCl at pH 7.5 were stored at −80 °C before use.

site, the amount of naloxone required to reverse the actions of Met[5]-enkephalin or morphine is a function of the affinity of the receptor for the ligands and their concentrations. The dissociation constant of naloxone, K_a, calculated[22] from the data in Fig. 3a and b is 3 × 10⁻⁸ M for reversal of Met[5]-enkephalin inhibition and 2 × 10⁻⁸ for reversal of morphine inhibition (see legend to Fig. 3). These values agree well with the dissociation constant of naloxone of 2 × 10⁻⁸ M previously determined by direct measurement of the binding of ³H-naloxone to the opiate receptor of the hybrid cells[14].

As Table 1 shows, Met[5]-enkephalin and morphine inhibit adenylate cyclase in homogenates prepared from NG108-15 hybrid cells, but not adenylate cyclase of the glioma parent, C6BU-1, which lacks narcotic receptors, or the neuroblastoma parent, N18TG2, which has fewer narcotic

Fig. 2 Time course of cyclic AMP formation by NG108-15 homogenates (97 μg per protein per tube) in the presence of 2 × 10⁻⁷ M morphine (○), 1.6 × 10⁻⁷ M Met[5]-enkephalin (●), or in the absence of added inhibitors (△). Assay conditions were as for Table 1.
receptors than NG108–15 hybrid cells[14,15]. These data, together with the naloxone reversal of enkephalin inhibition, show that both opiate receptors and enkephalin are required for the inhibition of adenylate cyclase activity.

The apparent inhibition constants for adenylate cyclase of Met[5]- and Leu[5]-enkephalins as well as morphine and some peptides which are fragments of enkephalin are summarised in Table 2. The K_i for Met[5]-enkephalin is 12–20 nM. Leucine enkephalin is three to six times less active an inhibitor than Met[5]-enkephalin and the enkephalin fragments tested had little or no effect on adenylate cyclase activity. In other experiments, not shown here, the di-and tripeptides did not antagonise morphine-dependent inhibition of adenylate cyclase. Met[5]- and Leu[5]-enkephalins are somewhat more potent inhibitors of basal, than PGE₁-stimulated adenylate cyclase. Morphine usually behaves similarly, although not in the experiment shown here. These observations show that opiate and PGE₁ receptors are functionally coupled either by allosteric interactions or by competition for the same site on the enzyme.

Compound	K_i^* (nM)	
	Basal	PGE₁
Tyr–Gly–Gly–Phe–Met (Met[5]-enkephalin)	12	20
Tyr–Gly–Gly–Phe–Leu (Leu[5]-enkephalin)	40	120
Morphine	1,500	1,500
Tyr–Gly–Gly	>1,000,000†	—
Gly–Gly–Phe	>1,000,000‡	—
Phe–Leu	>1,000,000‡	—

Adenylate cyclase activity was determined as described in the legend of Table 1.
*Concentration of peptide required for half-maximal inhibition of basal or PGE₁ (10^{-4} M)-stimulated adenylate cyclase. Maximal inhibition of adenylate cyclase activity usually is 30–60% of total activity[14].
†Slight activity at 10^{-3} M (0–20% inhibition of adenylate cyclase).
‡No inhibition at 10^{-4} M.

An important question, that can be studied with cultures of NG108–15 cells, is whether the endogenous opiate peptides are addictive. As reported previously[28,29], NG108–15 cells and perhaps animals as well[7] chronically exposed to morphine, become tolerant to and dependent on morphine due to its dual action in inhibiting adenylate cyclase and eliciting a gradual increase in adenylate cyclase activity which compensates for the inhibition. Experiments are in progress to test whether hybrid cells become tolerant to and dependent on enkephalin and other opiate-like peptides.

Opiate peptides, 5–31 amino acid residues long[30–34], as well as β-melanocyte-stimulating hormone (β-MSH) apparently are derived by proteolysis of a common precursor, β-lipotropin[31], which had been isolated from pituitary[32]. Thus, β-lipotropin is a precursor of both an activator of adenylate cyclase (β-MSH)[33], and inhibitors of this enzyme (opiate peptides). Presumably, β-MSH and the endogenous opiates are recognised by different species of receptor which may be on the same or on different cells. Thus, positive and negative responses could result in separate cells or a single cell from different peptides derived from the same precursor.

The endogenous opiate peptides seem to be neurotransmitters or hormones which are destined for neurones with opiate receptors. The opiate peptide-receptor complex is a potent inhibitor of adenylate cyclase and thus the activations of adenylate cyclase by other species of neurotransmitters and hormones are suppressed. In effect, the opiate peptides act as pleiotropic desensitisers of many kinds of receptors which, in concert with the corresponding ligands, activate adenylate cyclase. Prolonged exposure to the opiate peptides may lead to an increase in adenylate cyclase activity as previously observed with morphine and other narcotics[28,29]. Thus, the opiate peptides may regulate the perception of incoming messages by neurones with opiate receptors in both a negative and positive manner.

We thank Christian B. Anfinsen, Lila Corley and Urs. Th Ruegg for help and advice with peptide synthesis and purification, Richard A. Streaty for assays and Doyle Mullinax for growing cells.

Fig. 3 *a*, relationship between naloxone concentration and the reversal of adenylate cyclase inhibition by 0.01 (△), 0.1 (□), or 1 μM (●) Met[5]-enkephalin. Also shown is the relationship between naloxone concentration and adenylate cyclase in the absence of Met[5]-enkephalin (○). Assays were for 5 min with 87 μg of homogenate protein per tube. *b*, a similar experiment without morphine (○), or with 1 μM morphine (●); or 100 μM morphine (▽). Reaction mixtures (90 μg of homogenate protein per tube) were incubated for 5 min. Other assay conditions are described in the legend of Table 1. Equilibrium binding constants (K_e) for naloxone were calculated by finding the concentration of naloxone at which the adenylate cyclase activity, in the presence of the highest concentration of inhibitor, is equal to that measured in the absence of naloxone at an inhibitor concentration 100 times lower. This concentration of naloxone is, by the dose-ratio method[15], equal to 99 times K_e.

Our experiments show that endogenous opiate peptides can be assayed rapidly by determining the opiate-peptide-dependent inhibition of adenylate cyclase which is reversed by naloxone. The range of the assay is 0.2–5.0 pmol of Met[5] enkephalin per 100 μl of reaction mixture or 0.1–2.5 pmol per 50 μl of reaction mixture. Thus, we have found, in collaboration with Goldstein and Cox, that a peptide which has been purified extensively from pituitary tissue[24] and has a higher molecular weight than enkephalin is a potent inhibitor of both basal and PGE₁-stimulated adenylate cyclase of NG108–15 cells. Enkephalin antagonists can be assayed in a similar manner.

Molecular weights of antihaemophilic factor and von Willebrand factor proteins in human plasma

HUMAN factor VIII contains at least two biological activities, antihaemophilic factor (AHF) and von Willebrand factor (VWF). When highly purified, factor VIII is estimated to have a molecular weight of over 1.12×10^6, as determined by gel chromatography or sedimentation equilibrium centrifugation[1-4]. Some investigators[2-4] consider factor VIII a single glycoprotein with a number of covalently linked subunits. Since factor VIII can be dissociated in certain conditions, others[5-7] consider it to be a two-molecule complex consisting of a multi-subunit high molecular weight protein ($> 10^6$) with VWF activity that acts as a carrier molecule for a lower molecular weight (2.4×10^5) subunit with AHF activity. A third model suggests that both AHF and VWF are high molecular weight, separate proteins consisting of disulphide linked subunits[8,9].

These interpretations do not adequately explain certain clinical and laboratory observations. For example, von Willebrand patients infused with factor VIII preparations show a secondary rise in AHF activity when no measurable VWF activity or factor VIII-related antigen is present[10]. The molecular weight of the AHF proteins in this secondary rise, as determined by Agarose gel chromatography, showed that some AHF activity was associated with proteins with a molecular weight of at least 1×10^6 and some with proteins of considerably lower molecular weight; but neither protein showed VWF activity[11]. Furthermore, low molecular weight AHF has been found to aggregate with itself[8]. These findings could be interpreted more readily if native AHF and VWF proved to be two different molecules and the circulating AHF and VWF were low in molecular weight, comparable to that reported for the subunit size of reduced factor VIII.

Using rapid quantitative ultrafiltration of whole plasma to estimate the molecular weight of AHF and VWF and study their interactions, we determined that each native protein has a molecular weight of less than 300,000 and they exist in plasma as separate molecules.

Whole blood from healthy male and female adults was collected in 3.8% citrate (9:1). All subsequent processing steps were carried out at the specified experimental temperature.
Fig. 1 Linear relationships between percentage marker proteins in filtrate and molecular weight on 9 different XM100 membranes labelled A–I. Each point represents the mean of at least 10 determinations. ■, Albumin; ○, gamma globulin; ▲, β-glucuronidase; ●, urease; △, β-galactosidase.

Plasma low in platelets was prepared by two centrifugations for 5 min at 16,000g and used immediately.

New Amicon 25-mm diameter XM100 ultrafiltration membranes were routinely cleaned by ultrasonication (Millipore Ultrasonic Cleaner Model #XX66 008 00) for 60 min in distilled water before use and by sonication for 15 min in distilled water before each application of proteins. Each filter was calibrated by ultrafiltration of several enzymes and other protein markers of known molecular weight and recalibrated before each subsequent use. The same filter could be used many times and between uses was stored at 4 °C in distilled water. Other methods for preparing and cleaning the membranes, including those suggested by the manufacturer, proved unsatisfactory and experiments in which they were used were, in general, not reproducible.

Solutions of each protein molecular weight marker containing 1.0 mg ml^{-1} (100%) were individually ultrafiltered and the

The difference between the mean molecular weights calculated from the paired data is highly significant ($P < 0.001$).

filtrate was assayed for enzyme activity or protein concentration. The results were expressed as the percentage of the initial concentration per ml. The resulting calibration curves (Fig. 1) show a linear relationship between the percentage of protein recovered in the ultrafiltrate and the molecular weight. Each point represents the mean of 10 determinations on one of 9 different XM100 membranes. The precalibrated ultrasonicated membranes could thus be used to determine the molecular weights of various proteins from 68,000 to ~600,000, without loss of biological activity.

The first ml of ultrafiltrate was collected from 3.0 ml of fresh plasma filtered at 37 °C under nitrogen (10 pound/inch[s]). The filtrate and retentate were then examined for AHF activity (two-stage assay)[12], ristocetin VWF activity[13,14], and factor
Fig. 2 Molecular weight of AHF and VWF determined from the percentage of fresh plasma in the ultrafiltrate in a single typical experiment using membrane E. Marker proteins and plasma were filtered through an XM100 membrane at 37 °C under nitrogen (10 pound/inch[r]).

VIII-related antigen (radioimmunoassay)[15]. Between the filtrate, the retentate and the material trapped on the filter support, virtually all the AHF or VWF activity in the sample could be accounted for.

In these conditions, 53% of AHF and 47% of VWF and antigen activity were recovered in the ultrafiltrate in a typical experiment. As evident from the calibration curve, the percentage of AHF or VWF in the ultrafiltrate corresponded to a molecular weight of 240,000 for AHF and 270,000 for VWF (Fig. 2). With use of a number of different calibrated membranes, a mean molecular weight of 236,000±12,000 for AHF and 280,000±15,000 for VWF was determined (Table 1).

The fact that the AHF and VWF in the 1 ml of filtrate was not a selected portion of the proteins in the 3 ml of sample applied was demonstrated when all 3 ml of plasma were filtered through a 43 mm instead of a 25 mm diameter membrane and similar molecular weight values were obtained.

To assess the effect of prolonged incubation on the filterability (molecular weight) of AHF and VWF, fresh plasma was incubated at 37 °C, and samples were assayed periodically. The proteolytic inhibitors Trasylol (50 kI Units ml⁻¹) and benzamidine (2×10⁻³ M) were added to prevent degradation of proteins during the experiment. After 6 h of incubation, the apparent molecular weight of AHF increased from 240,000 to 380,000 whereas the apparent molecular weight of VWF increased from 280,000 to more than 600,000. This increase was

attributed to aggregation of the AHF and VWF in vitro. The rate of aggregation proved to be faster at lower temperatures (25 or 4 °C).

Since the rate of aggregation appeared to increase with time and at low temperature, it was not surprising that the ultrafiltrates of cryoprecipitate and two commercial factor VIII preparations contained no measurable AHF or VWF activity, both of which were found in the retentate.

In summary, we have shown that the molecular weights of AHF and VWF in fresh human plasma are ~240,000 and 280,000. Their different molecular weights and rates of aggregation suggest that they are separate proteins, a conclusion consistent with other data from our laboratory using solid-phase polyelectrolyte fractionation. High molecular weight factor VIII seems to be an artefact arising from blood processing, low temperature storage, or fractionation procedures.

Quantitative ultrafiltration offers an important new method for the rapid, non-destructive estimation of the molecular weight of microgram quantities of proteins.

N-terminal amino acid sequences of variant-specific surface antigens from *Trypanosoma brucei*

THE major pathogenic African (salivarian) trypanosomes can evade the immune response through a process of antigenic variation (reviewed in ref. 1). Mainly due to Gray's work[2,3], this variation is thought to be phenotypic—involving sequential expression of alternative genes and not resulting from contemporaneous mutation. The capacity for variation which exists within a clone, isolate or species, or within strains circulating within a geographical area, is uncertain (though probably extensive) and is relevant to an evaluation of the feasibility of developing vaccines. Although serotyping of trypanosome populations has been refined through the use of fluorescence methods[4,5], there is a need to characterise the relevant antigens and investigate the molecular basis of antigenic variation. Other workers[6–9] identified putative variable antigens and found them to be soluble glycoproteins[10–13], probably located in the surface coat[13,14]. The antigen preparations obtained, however, were generally heterogeneous, frequently unstable or in low yield. A recent report[15] described the complete purification in good yield of individual variant-specific surface antigens (VSSAs) from a series of clones of *Trypanosoma brucei*. The VSSAs seem to be the primary

Fig. 1 Amino terminal sequences of variant-specific surface antigens from four successive trypanosome variants. Sequences were obtained by automated liquid-phase and solid-phase techniques (see text). Phenylthiohydantoin derivatives were identified by high-pressure liquid chromatography on a column of microbondapak-C_{18} reverse-phase support (Waters Associates) using a Waters liquid chromatograph fitted with an ultraviolet detector. Solvent 1 was water–methanol–acetic acid (90:10:0.25), pH 4.1, and solvent 2 was water–methanol–acetic acid (10:90:0.025). A linear gradient of 95% solvent 1:5% solvent 2 to 40% solvent 1:60% solvent 2 was run at a flow rate of 2 ml min^{-1}. Normal sample quantity was 1–5 nmol, but where less sample was available, acetone was added to solvent 1 (50 µl l^{-1}) to give a flat baseline at high detector sensitivity. Identifications were confirmed by either thin-layer chromatography (all residues except His and Arg for positions 1–25), gas–liquid chromatography (non-polar residues) or amino-acid analysis after back-hydrolysis with HI (all residues except Trp and Met) (for details see ref. 19). Average repetitive yield was 93.5%. Residues in italics are interim assignments.

mediators of antigenic variation in *T. brucei*. Each antigenically homogeneous trypanosome clone yields one predominant glycoprotein antigen composed of a single polypeptide chain (apparent molecular weight 65,000 as determined by sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis) and, depending on the variant, 7–17% (w/w) carbohydrate (unpublished results of J. G. Johnson). The VSSA seems to be the major or sole constituent of the surface coat and comprises 5–10% of the total cell protein. Studies of the amino acid sequences, carbohydrate constitution and cell-surface organisation of several VSSAs are in progress, and we report here the N-terminal amino acid sequences of VSSAs isolated from four closely related variants.

Antigens were purified as described previously[15], from a series of clones prepared from cell populations isolated during 3 weeks from a single rabbit infected with a cloned strain (427) of *T. brucei*. N-terminal sequences (Fig. 1) were generally determined on approximately 8-mg amounts of intact S-^{14}C-carboxymethylated antigens using a dilute Quadrol programme[16] in a Beckmann 890C sequencer. Runs were performed in duplicate. The sequence of variant II was identical in two samples purified on separate occasions. Limited tryptic digestion (unpublished results of G. A. M. C. and J.G. Johnson) of variants I and III produced in each case a single large fragment of molecular weight 48,000 and 45,000, respectively (estimated from SDS–polyacrylamide gel electrophoresis). After purification on Ultrogel AcA 54 (variant III) or by isoelectric focusing (variant I), 1 mg of each tryptic fragment was attached to 3-aminopropyl glass using phenylene diisothiocyanate[17] and was degraded in an LKB 4020 solid-phase sequencer using a single cleavage programme (LKB Biochrom Ltd) similar to that described by Laursen[18]. The N-terminal sequences of these fragments from variants I and III were identical to the respective intact proteins through residues 2–15. The results for variants I and II extend and confirm those obtained previously using a micro solid-phase technique[17].

These results confirm the homogeneity of the purified antigens and demonstrate an absence of sequence homology in the N-terminal region. Sequential cleavage techniques generally permit identification of the initial 30–40 residues of an intact protein. This represents only 6% of the VSSA molecule. Future work, involving subfractionation of the antigen, will extend these sequences and may reveal homologies in other regions of the molecules. Other evidence (unpublished results of G. A. M. C. and J. G. Johnson) however, suggests that extensive variation occurs along most of the polypeptide chain, but that nevertheless there may be some conservation of tertiary structure, as indicated by the characteristics of selective tryptic cleavage of the native antigens. The isolation of large tryptic fragments with intact N-terminal regions containing several lysine residues from variants I and III suggests that the N-

terminus of the native VSSA is relatively protected from proteolytic attack. This observation, coupled with the reproducibility of sequences obtained with different preparations of VSSA, makes it likely that the reported sequences represent the true N termini of the intact antigens.

Except in respect of their lack of homology, the reported sequences are without intrinsically striking features. The amino acids are present in proportions which reflect the overall VSSA amino acid compositions. Even if the amino acid sequences of the VSSAs analysed in the study reported here are later shown to be atypically hypervariable, it seems that evolution of the genes responsible for successive variant types is a consequence of the accumulation of countless mutations. Our continuing structural studies are focusing on a search for regions of constant (or less variable) sequence which we hope will provide clues to the evolution of these antigens and also clarify the features necessary for their integration into the trypanosome surface membrane.

This work was performed in part at the Department of Microbiology, University of Alabama Medical Center, Birmingham, Alabama.

Enzymatic synthesis of deoxy-5-methyl-cytidylic acid replacing deoxycytidylic acid in *Xanthomonas oryzae* phage Xp12 DNA

PHAGE Xp12 on *Xanthomonas oryzae* was isolated from the irrigation water of a rice field. In the DNA of this phage, cytosine is completely replaced by 5-methylcytosine[1]. Isotope tracing studies on the biosynthesis of this unusual pyrimidine demonstrated that methylation of this cytosine is different from that of the 5-methylcytosine which is found in trace amounts in most plant and animal DNAs. The latter is methylated by methionine. On the other hand, the methyl group of 5-methylcytosine residues of Xp12 is derived from the 3-carbon of serine and not from the thiomethyl carbon of methionine[2]. In this investigation, the synthesis of deoxy-5-methylcytidylic acid (d5MCMP) was found to take place at the level of nucleotide, with deoxycytidylic acid (dCMP) and formaldehyde as substrates in the presence of 5,6,7,8-tetrahydrofolic acid (THFA) and an enzyme preparation from *X. oryzae* infected with Xp12 phage. This reaction seems to account for the synthesis of the unique pyrimidine, 5-methylcytosine, which occurs in the DNA of phage Xp12.

Exponential phase *X. oryzae* strain 604 grown in PS medium[3] (potato, 200 g; peptone, 5 g; sucrose, 15 g, Ca(NO₃)₂.4H₂O, 0.5 g; Na₂HPO₄.12H₂O, 2 g in 1 l of distilled water) was infected with a fivefold excess of Xp12, which has a latent period of 120 min in these conditions; aeration was continued for 40 min after infection. The cultures were rapidly chilled to 2 °C and the organisms were collected by centrifugation. After washing and resuspension in 0.05 M Tris-HCl buffer, *p*H 7.5, the cells were disrupted by using a Blacktone Model BP-2 Ultrasonic Probe. Unbroken cells and other particles were removed by centrifugation at 8,000*g* for 5 min. The supernatants were dialysed against 0.05 M Tris-HCl, *p*H 7.5 at 4 °C for 4 h. To show the induction by the phage of synthesis of the enzyme with methylating activity, protein synthesis was inhibited by the addition of chloramphenicol (30 μg ml⁻¹) just before phage infection. Extracts from uninfected and chloramphenicol-treated bacteria were prepared by the same method from parallel cultures. The protein concentration was approximately 13 mg ml⁻¹ as measured by the method of Lowry *et al.*[4].

The reaction mixture (150 μl) contained 50 μl enzyme extract, 10 μmol dCMP, 0.8 μmol THFA, 2 μmol ¹⁴C-formaldehyde (2 m Ci mmol⁻¹), 50 μmol MgCl₂.6H₂O, 32 μmol 2-mercaptoethanol and 40 μmol Tris-HCl, *p*H 7.5. The mixtures were incubated at 30 °C for 30 min. The reaction was stopped by adding 150 μl of 1.0 M sodium acetate, which dissociated 'active formaldehyde' to formaldehyde and tetrahydrofolate[5], followed by 100 μl of 0.4 M dimedone (in 50% ethanol) to precipitate formaldehyde[6]. The mixture was heated in boiling water for 5 min and the precipitated protein and formaldehyde were removed by centrifugation at 8,000*g* for 5 min. The supernatant and authentic d5MCMP, prepared from Xp12, were applied respectively to Whatman No. 1 chromatography paper and developed with isopropanol–HCl–H₂O (65: 16.6: 18.4).

Table 1 shows that the extract of infected cells promotes the synthesis of d5MCMP. A sharp peak of radioactivity was detected at the position corresponding to authentic d5MCMP. For general enzyme assays, the area round the peak was cut out from the paper, placed in a vial, and the radioactivity counted with a Packard Model 3375 scintillation spectrometer. To identify the reaction product, the spot containing the radioactivity was cut out and eluted with water. The eluate was dried and hydrolysed with 50 μl of 90% formic acid at 175 °C for 30 min. Acid hydrolysis of the nucleotide yielded a base with *R*f identical to that of authentic 5-methylcytosine in three solvent systems: isopropanol–HCl–H₂O (170 : 40 : 39), *n*-butanol–H₂O (86 : 14) and *n*-butanol–H₂O (86 : 14) with 5% NH₄OH in air. For further identification, a small amount of the substance obtained by evaporation of the eluate from a chromatogram spot was deaminated with HNO₂. Deamination was carried out by adding 50 μl of 2 M NaNO₂ and 10 μl of glacial acetic acid to the eluate. After standing overnight at 25 °C, the solution was applied directly to Whatman No. 1 paper. A sample of authentic 5-methylcytosine was treated in the same way. Both the unknown and authentic 5-methylcytosine were found to convert into a substance identical to thymine in its chromatographic properties.

On the basis of these observations, we conclude that an enzyme found in the infected bacteria catalyses the direct methylation of dCMP, but that this enzyme, deoxycytidylate methyltransferase, is absent from uninfected cells. The reaction required the presence of THFA and Mg²⁺, in addition to dCMP and formaldehyde as substrates. Deoxy-5-methylcytidylic acid can thus be synthesised in phage Xp12-infected *X oryzae* by the following reaction

$$\text{dCMP} + \text{HCHO} \xrightarrow{\text{THFA, Mg}^{2+}} \text{d5MCMP}$$

Definitions of free energy levels in biochemical reactions

IN considering the energetics of an enzyme-catalysed reaction it is of interest to enquire into what constitutes the "drive", in a thermodynamic sense, for the reaction, particularly when the enzyme is involved in an energy-coupled process. This often

arises when speculations are made on the operation of a system on the basis of equilibrium constants for the reaction scheme determined on the system, or fragments of it, *in vitro*. In the case of active transport or muscular contraction the free energy for transport or contraction is derived from the hydrolysis of ATP and the overall drive arises because the chemical potential of ATP is greater than that of its products (ADP and P_i) at physiological concentrations. But to understand how the drive is expressed in the mechanism of such processes it is necessary to consider and define the relative free energy levels of the intermediates of the reaction. The free energy and standard free energy as normally defined as not sufficient for this purpose. They both, in general, refer to the system as a whole and are used in the context of free energy changes involving substrates, products and ligands. The drive of the system, in the sense used here, is to be sought in the relative disposition of the free energy levels of an individual (time-averaged) macromolecule and in the manner in which these levels favour (stochastically) a particular direction of the flux in what may be a complicated reaction scheme. We refer to these free energy levels of individual macromolecules as the "basic" free energy levels. To avoid confusion we have termed the overall free energy change of the whole system for a given transition as the "gross" free energy change. The definitions of and relationships between the standard, basic, and gross free energy levels for a system of macromolecules (either in free solution or immobilised) are given below, together with a simple example relevant to muscular contraction. A more mathematically detailed version of this work with more complicated examples for both muscle and active transport has been published elsewhere[1,2].

We consider a macromolecule (for example, enzyme) which can exist in a number of states (for example, enzyme-substrate, enzyme-product). In free solution, dilute with respect to enzyme, the chemical potential of the *i*th state can be written (per molecule and neglecting the activity coefficient) as

$$\mu_i = \mu^0_i + kT \ln c_i \qquad (1)$$

In the case of active transport and of muscle, the macromolecule is bound and the chemical potential can be derived from statistical mechanics[1] as

$$\mu_i = A_i + kT \ln p_i \qquad (2)$$

where A_i is the Helmholtz free energy of one macromolecule in the *i*th state and p_i is the probability of occupancy of this state ($\sum_i p_i = 1$). As this expression is the more general we shall use it throughout, noting for the free solution case that $c_i = bp_i$ and $A_i = \mu^0_i + kT \ln b$, where b is a constant. (In the bound macromolecule case, A_i is essentially the same as the Gibbs free energy G_i since the two quantities differ only by a negligible pV_i term.)

The free energy change for a transition between two states *i* and *j* of a macromolecule E can now be defined (for a kinetic scheme which may have a large number of steps and hence states of *E*). For generality, consider a transition involving the binding of a ligand (or substrate, and so on)

$$\begin{array}{c} \alpha^*_{ij} \\ E + L \rightleftharpoons EL \\ \alpha_{ji} \end{array} \qquad (3)$$

where E and EL are the *i*th and the *j*th states respectively, α^*_{ij} is

the (second order) forward rate constant and α_{ji} is the (first order) reverse rate constant. (The asterisk replaces the prime used previously[1-4] to denote second order quantities, to prevent confusion with the different assignment of the latter as below.)

The standard free energy change is

$$\Delta\mu^0_{ij} = A_i + \mu^*_L - A_j \qquad (4)$$

Note that we use Δ in the unconventional sense (initial) − (final), to make most such quantities used below positive.

The basic free energy change is

$$\Delta A'_{ij} = A_i + \mu_L - A_j \qquad (5)$$

The gross free energy change is

$$\begin{aligned} \Delta\mu'_{ij} &= \mu_i + \mu_L - \mu_j \\ &= \Delta A'_{ij} + kT \ln(p_i/p_j) \end{aligned} \qquad (6)$$

The meaning given to the prime here is as follows: A_i and A_j can be considered as the free energy levels of individual macromolecules, but where binding of a ligand occurs one of them must be "corrected" for the actual (not "standard") ligand concentration if they are to be compared[3,4]. Thus we can write $A'_E = A_E + \mu_L$, or more generally $A'_i = A_i + \mu_L$, and the use of the prime implies that the As have been "corrected" where appropriate.

The standard free energy change can be determined if the conventional equilibrium constant ($K^*_{ij} = \alpha^*_{ij}/\alpha_{ji}$) for the transition is known, since

$$\Delta\mu^0_{ij} = kT \ln K^*_{ij} \qquad (7)$$

Note that the asterisks refer to the "second-order" quantities.

It is worth noting that for most biological reactions in free solution the standard and gross free energy changes are, of course, simply related to the corresponding standard and "actual" molar Gibbs free energy changes, that is, $-\Delta G^0_{ij} = N_0\Delta\mu^0_{ij}$ and $-\Delta G_{ij} = N_0\Delta\mu'_{ij}$, where $N_0 \equiv$ Avogadro's number and the Δ on the left in both cases is the customary $\Delta \equiv$ final − initial. We approach these changes, however, from the unconventional point of view of single transitions between free energy levels of macromolecular states on a pseudo-isomeric basis and it is appropriate to consider the changes on a "per molecule" basis.

It is easily shown that the basic free energy change is given by

$$\Delta A'_{ij} = kT \ln c_L K^*_{ij} = kT \ln K_{ij} = kT \ln(\alpha_{ij}/\alpha_{ji}) \qquad (8)$$

where $K_{ij} = c_L K^*_{ij}$, and $\alpha_{ij}(= c_L\alpha^*_{ij})$ is the pseudo-first-order rate constant for the transition in question.

Thus, "correcting" for ligand concentration yields first-order rate constants and the corresponding (basic) equilibrium constants, which can be treated as if the transition occurred between isomers of the macromolecule.

Since the basic free energy change refers to the difference between the free energies of states of a single macromolecule,

and hence influences its stochastic behaviour, it is of fundamental importance in determining the drive in a reaction sequence. A diagram of the relative basic free energy levels (see Fig. 1) is, as shown above, closely related to the kinetic description in terms of first-order rate constants (though energy barriers between states are not shown in Fig. 1). Thus a downwards change favours flux through the system in the direction of the

basic change by a term $(kT \ln p_i/p_j)$ in equation (6). This is a typical "concentration" term of purely entropic origin. A situation may thus arise where the basic free energy change between two successive states is small, but the gross free energy change is large. (This can occur in an enzymatic cycle when the transition $i \rightarrow j$ is the rate-limiting step, so that in the steady state $p_i \gg p_j$. An example of this is given below.)
Fig. 1 Free energy levels for the intermediates in the hydrolysis of ATP by myosin *S1* (*M*) at 20 °C. Concentrations of ATP, ADP and P_i were chosen as 3 mM, 0.03 mM and 1 mM respectively. $\Delta\mu^0{}_{ATP}$ was taken as 11.2 kT. M + ATP was arbitrarily set at the same free energy level in (*a*), (*b*) and (*c*). Intermediates in parentheses belong to sets of levels immediately above or below those shown in the figure. The numbers opposite gross free energy levels (*c*) are the steady-state occupancies (p_i).

overall drive (ATP→ADP+P$_i$) whereas an upwards change opposes it. It is the downward basic changes that constitute the stochastic drive at the level of the intermediates in a reaction.

As for the standard free energy, in the case of transitions where the binding of ligands, and so on is not involved (isomeric transitions such as $ES \rightleftharpoons EP$), the standard free energy change is easily seen to be numerically identical to the basic change. But in non-isomeric transitions the two are by no means the same; in fact, the standard free energy change is of little interest as it refers to ligand, and so on at molar (that is "standard") concentration. Similarly the basic (isomeric) equilibrium constant K_{ij} is more relevant to actual conditions than the "standard" equilibrium constant $K^*{}_{ij}$.

The gross free energy change can be calculated when the probabilities (or concentrations) of the intermediates are known, in addition to the equilibrium constants. It gives the Gibbs free energy change that actually occurs in a transition when the whole system is considered. This is to be contrasted with the basic change description in which a single macromolecule undergoes transitions stochastically[5] and is "unaware" of the rest of the system. Thus the gross change is related to the overall flux and entropy production in a transition[1,2]. It should be noted that, for given substrate, and so on, concentrations, the basic changes and levels are invariant whereas the gross changes depend on the exact conditions of the system (in the steady state or during transients).

The gross free energy change for a transition differs from the

Suppose now that these states are coupled to another reaction, to transport or, in the case of muscle, to the performance of mechanical work; it might be deduced that the coupled process is being "driven by the concentration term". This would, in general, be incorrect; the efficiency and flux of a coupled process that is far from equilibrium result from the detailed kinetics of the entire cycle of the driving reaction and the kinetic constraints imposed on it by the coupled process.

For an enzyme which hydrolyses ATP, in each completed cycle the decrease in free energy is given by the sum of either the basic or the gross changes, that is

$$\Delta\mu_{ATP} = \Sigma\Delta A'_{ij} = \Sigma\Delta\mu'_{ij} > 0 \qquad (9)$$

The free energy decrease per molecule of ATP hydrolysed is given by

$$\Delta\mu_{ATP} = \Delta\mu^0{}_{ATP} + kT \ln(c_{ATP}/c_{ADP}c_{P_i}) \qquad (10)$$

Here again the standard free energy change is of no direct interest.

A comparatively simple example related to muscular contraction will now be given to illustrate the different definitions. (More complicated models both of active transport and of muscle are discussed in refs 1–3). The kinetic scheme for the hydrolysis of ATP by myosin subfragment 1 (M) has been determined[6–8] as

$$M + ATP \xrightleftharpoons[2.2 \times 10^5 s^{-1}]{10^8 M^{-1} s^{-1}} M \cdot ATP \xrightleftharpoons[2.3 \times 10^{-6} s^{-1}]{400 s^{-1}} M^* \cdot ATP \xrightleftharpoons[17.8 s^{-1}]{160 s^{-1}} M^{**} \cdot ADP \cdot P_i$$

$$3.8 \times 10^{-3} s^{-1} \Big\Updownarrow 0.06 s^{-1}$$

$$M + ADP \xrightleftharpoons[2.7 \times 10^4 s^{-1}]{10^8 M^{-1} s^{-1}} M \cdot ADP \xrightleftharpoons[1.4 s^{-1}]{400 s^{-1}} M^* \cdot ADP \xrightleftharpoons[7.3 \times 10^5 s^{-1}]{10^8 M^{-1} s^{-1}} M^* \cdot ADP \cdot P_i$$
where the rate constants for binding ATP, ADP and P_i have been chosen as $10^8 \, M^{-1} s^{-1}$ and the forward rate constant for the third step represents the minimum likely value. Assuming reasonable values for the physiological concentrations of ATP, ADP and P_i, the relative free energy levels between states can be calculated, taking the steady-state case for the gross free energy changes (Fig. 1).

As noted above, the magnitude of free energy changes for the standard and basic diagrams coincide only for isomeric transitions (for example, $M \cdot ATP \rightleftharpoons M^* \cdot ATP$). As regards the difference between the basic and gross diagrams, the former has both upward and downward transitions, the principal downward changes being for the two-step binding of ATP. The free energy changes for the gross diagram are all downward. This is a natural consequence of the steady state in a single cycle in which the flux through the system is unidirectional[1]. The largest free energy change is for the two-step binding of ATP in both the basic and gross diagrams, but in the gross diagram there is not inconsiderable change at the rate-limiting step ($M^{**} \cdot ADP \cdot P_i \rightleftharpoons M^* \cdot ADP \cdot P_i$). This is a consequence of the build-up of the occupancy of the state preceding the rate-limiting step. In the gross diagram several pairs of states are at nearly the same free energy level indicating that, in the steady-state conditions used, these pairs are essentially in equilibrium (indeed, when this is considered in conjunction with the sparsity of occupation of the states M, $M \cdot ATP$ and $M \cdot ADP$, the scheme reduces essentially to a two-state energetic and kinetic process consisting of $M^* \cdot ATP$ "lumped" with $M^{**} \cdot ADP \cdot P_i$ and $M^* \cdot ADP \cdot P_i$ "lumped" with $M^* \cdot ADP$). In all the diagrams, for each cycle completed, the subsystem or system progresses to another, identical, set of levels shifted downwards from the previous set by $\Delta\mu_{ATP}$ ($\Delta\mu^0_{ATP}$ for the standard diagram).

The S1 scheme provides considerable scope for speculation about the basic free energy levels of the cyclic interaction of myosin with actin in the crossbridge mechanism of muscular contraction. Unfortunately full details of the corresponding scheme in the presence of actin are not yet known; also there are serious difficulties in translating a kinetic scheme derived for free solution to that for the intact myofibrillar matrix[10]. Nevertheless, modifying slightly a much simplified scheme for actomyosin[11],

$$M^{**} \cdot ADP \cdot P_i \rightleftharpoons M^* \cdot ATP$$

$$\Updownarrow \, \circlearrowright \, \Updownarrow$$

$$AM \cdot ADP \cdot P_i \rightleftharpoons AM$$
the M and AM states correspond respectively to detached and attached states of crossbridges in muscle and the drive (and directionality) of contraction must be reflected in the downward progression of basic free energy levels between successive AM states in the (biochemical) actomyosin scheme[3,12]. Large downward changes elsewhere in the cycle could lead to a waste of free energy in the gross free energy representation for intact muscle. It seems that such changes may not exist, at least in the basic representation for the actomyosin scheme (H. D. White and E. W. Taylor, in preparation); for example, the dissociation constant and hence the basic free energy change for $AM + ATP \rightleftharpoons A + M^* \cdot ATP$ is small, the large binding energy for ATP to myosin being offset by that of actin to

myosin[13]. Furthermore, the basic change for $M^* \cdot ATP \rightleftharpoons M^* \cdot ADP \cdot P_i$ is comparatively small (Fig. 1). It is therefore possible to regard $M^{**} \cdot ADP \cdot P_i$ as a "high energy state", in relation to the last attached state (AM) in the scheme above, in the sense that the (probably) large downward basic free energy change between them serves as the drive for contraction (although it seems unlikely that all the available energy from ATP hydrolysis is conserved in the state $M^{**} \cdot ADP \cdot P_i$; compare ref. 14).

Gray[15] has argued on quantum mechanical grounds for an irreversible step in the crossbridge cycle. This invites the comment that it all depends on what you mean by irreversible; as we have argued above, it does seem that a necessary requirement for a high efficiency in muscle is a large downward basic free energy change from the state prior to attachment to the last attached state (measured in the latter in the absence of mechanical constraints), but that does not necessarily mean that the transitions would be entirely irreversible. However, a full treatment of this kind of problem involves the averaging of rate constants and free energy levels over the distribution of crossbridges in each attached state[3]. The actual system considered (for comparison with experiment) is not a single crossbridge but a macroscopic ensemble of crossbridges under a potentially wide distribution of mechanical constraints; there is no simple way of introducing these constraints, for example, by introducing a work-dependent opposing thermodynamic flux into the scheme (compare ref. 16). We hope to return to this problem in a future paper.

Finally, it should be stressed that a basic free energy diagram gives no more than a useful summary of the energetic situation for a single macromolecule. This may be useful in model-building[3] or in comparing different systems, but a full description of the energetics of a system in particular conditions requires a detailed knowledge of the kinetics of the system to generate (and understand) the gross free energy diagram.

This subject is treated in more detail and in a much more general context elsewhere[9].

reviews

Introducing HLA

Heather M. Dick

The HLA System: An Introductory Survey. (Monographs in Human Genetics, Vol. 7.) By A. Svejgaard *et al.* Pp. viii + 103. (Karger: Basel, London and New York, 1975.) SF/DM 38; $14.75.

THIS is an excellent little volume which sets out with a refreshing lack of pretentiousness to give a simple introduction to the HLA system. The authors certainly achieve their main purpose and offer a text which will be invaluable to those who wish to gain access to exciting new developments.

The HLA antigens are no longer the specialised subject of a few devoted transplantation workers. The wide range of problems in biology and clinical medicine which can be related to the major histocompatibility system is evidence of the explosion of knowledge which has occurred in this subject.

After a clear exposition of the components of the HLA system, in particular the genetics, we are led straight into the most recent and exciting work on the similarities between human and mouse immune response mechanisms. The section on biochemistry is brief— reflecting the paucity of information on this aspect until very recently, but introducing the reader immediately to newer and more rewarding developments on the structure of HLA substance. The practical applications of studies on HLA antigen frequencies are dealt with adequately enough for the general reader.

The authors are perhaps too modest in not including more of their own excellent work on the statistical and technical problems of estimating associations between specific HLA antigens and diseases. They also shy away from a detailed discussion of the mechanisms which might be responsible for such asociations. Although they list several impeccable reference sources dealing with this problem, it would probably be helpful to readers who are not intimately involved in the current work to have the arguments for and against the suggested hypotheses presented in some detail. Perhaps the authors felt they had already made it obvious that their preference was for the genetically de-

termined "immune-response gene" hypothesis, but it would not weaken their argument to expose the other hypotheses of molecular mimicry, or HLA as virus receptor to the cold light of print.

The final section on methodology is adequate to provide background information for those not directly concerned with technique, although the difficulties of explaining MLC typng to an uninitiated audience are painfully obvious. There is a very full bibliography to complete the text.

The materal presented is up-to-date and the authors are to be congratulated

on presenting a useful and readable volume which includes so much contemporary material. Textual misprints are a minor source of annoyance. The occasional lapses from colloquial English by the team of Danish authors might have been edited out, but do not detract in any way from the value of the book. Certainly, this reviewer could not hope to do as well in Danish. □

Hückel model

The HMO Model and Its Application. Vol. 1: Basis and Manipulation. By Edgar Heilbronner and Hans Bock. Pp. xv + 454. (Wiley: London and New York; Verlag Chemie: Weinheim, February 1976.) £16; $35.20.

THIS is the first volume of a three-volume treatise which is intended to acquaint "the practically oriented chemist having a relatively modest mathematical background" with the principles of the Hückel molecular orbital (HMO) model and with the simple techniques with which it can be used to obtain approximate but very useful qualitative results without recourse to a computer. Volume 1 contains all the theory and applications, and 250 problems; volume 2 will contain the solutions to the problems; and volume 3 will contain HMOs and derived quantities for simple π-elecfron systems.

This all seems splendid, but I cannot recommend the practically oriented chemist to rush out for his copy, and I doubt whether he would if I did. One reason is that this volume alone costs £16, so that the whole set is going to add up to a lot of money. Furthermore, for all that the authors claim to "fit the intuitive conceptual world of the chemist", there is not really very much discussion of the chemistry. Coulomb integrals, for instance, appear as numbers, with due acknowledgement to Streitwieser but no attempt to relate

their values to the chemist's notion of electronegativity, which indeed is not mentioned anywhere. More seriously, the treatment of reactions is now badly out of date, the book being an unrevised translation of the 1968 German edition; it is a great pity that the opportunity was not taken to add, for example, an account of the frontier orbital method, which has proved so fruitful in recent years.

Other cricitisms, which I make with some reluctance because I am in sympathy with the authors' intentions and find a great deal of useful material here, are that the style is intensely turgid and polysyllabic, and that some mathematical derivations are given in painful detail, whereas other results are quoted without the proof which might quite easily have been given. Finally, I disagree myself with the authors' policy of saying very little indeed about the deficiencies of the HMO model and about the way they can be overcome in more elaborate methods.

I do not underestimate the difficulty of putting molecular orbital theory over to the non-mathematical chemist. This is not a bad book by any means, but it is too heavy, too expensive and too late.

Cell handbook

Cell Biology. (Biological Handbooks, 1.) Compiled and Edited by Philip L. Altman and Dorothy Dittmer. Pp. xix+454. (Federation of American Societies for Experimental Biology: Bethesda, Maryland, 1976.)

FROM time to time a new book appears which is not simply a rehash of those that have gone before. Until now, biology has lacked its "Beilstein" and it is often a time-consuming business to find some small piece of information which you know has been published. This book compresses the maximum amount of factual information into the minimal space and at the same time gives key references from which a quick general overview of the field of interest may be made To give some examples, do you want to know what nutritional mutants of mammalian cells are available; 31 types are listed and 40 references are given to the field, all in the space of 2 pages. Are you interested in cloning mammalian cells; 52 examples are given and 49 references in only 3 pages. How long would it take to find the oxygen consumption of 618 different mammalian tissues; it is all here

with 198 references compressed into 17 pages. As this one volume extends to 400 pages, excluding appendices and a full index, the amount of information available is remarkable.

Some sample headings, similar in range to those listed above, will give an indication of the scope of this miniature encyclopaedia: resting cell membrane protentials, rheological properties of cells, changes in cell surface membranes with malignant transformation, permeability of inner mitochondrial membrane to anionic substrates, gross chemical composition of microsomes, occurrence of microfilaments in non-muscle cells and tissues, DNA content of cell nuclei. Obviously this is not a book that can be read but it is a book which most biologists are likely to treasure. Inevitably the choice of key references is open to criticism and at times the choice seems somewhat parochial. Nevertheless sufficient are given to enable the research worker to get off to a flying start

This series is likely to be a must in many libraries. **T. S. Work**

Dr Work is Head of the Division of Biochemistry at the National Institute for Medical Research, London, UK.

Somatic cell genetics

Variation, Senescence and Neoplasia in Cultured Somatic Cells. (A Commonwealth Fund Book.) By John W. Littlefield. Pp. xi+163. (Harvard University: Cambridge, Massachusetts and London, 1976.) £6.15.

THOSE of us who work in the field that is now somewhat pretentiously called somatic cell genetics owe John Littlefield a great deal. This little book puts us further in his debt. It is based on a course taught by him at Harvard over a number of years. The students who were exposed to this teaching can count themselves fortunate. The information presented is constantly subjected to the sort of critical assessment that can be provided only by someone who has himself worked long and intelligently in the field.

As its title indicates, the book has three main themes. The chapters dealing with genetic and other forms of variation in somatic cells and those dealing with the phenomenon of 'senescence' *in vitro* are difficult to flaw. The discussion of senescence, in particular, is informed by a degree of perception that I have not found

matched in any other published account of this subject.

I hope I may be forgiven for saying that I found the treatment of neoplasia less good. I think this may be because the author has not himself had so much experience of work with tumours; whereas, of course, he has made monumental contributions to the study of cells *in vitro*. In discussing experiments on somatic cells growing *in vitro*, he is very conscious of the quantitative aspects of the work he is describing, and especially of quantitative deficiencies in the evidence presented. His assessment of experiments dealing with the formation of tumours is, however, less sure If he had treated the relationship between 'transformation' and tumorigenicity with the same rigour as characterises his analysis of mutagenesis in somatic cells, I doubt whether he would have written (Established) "heteroploid lines appear to have lost growth control and to have become neoplastic". Even so, there's no chapter in this book that isn't worth reading, and there is, as a very important bonus, an absolutely splendid bibliography. **Henry Harris**

Henry Harris is Professor of Pathology at the University of Oxford, UK.

obituary

The recent premature and unexpected death of **James Olds** deprives physiological psychology of one of its most distinguished workers and the neurosciences of a man whose experimental work cannot be ignored in any serious behavioural theory. His major discovery provoked controversy from the time of its first report and although he made substantial contributions himself, many related issues are unresolved at the time of his death.

In 1953 Olds and P. M. Milner, working in D. O. Hebb's laboratory at McGill reported that rats with electrodes in lateral hypothalamic and septal sites would press a lever to deliver trains of stimuli to their own brains. Electrical self-stimulation revealed the existence of powerful central reward mechanisms and immediately raised difficulties for theories in which behaviour is initiated only to mitigate the aversive consequences of internal disequilibrium. The phenomenon had not been predicted by theories current at the time (but the aversive effects of brain stimulation had been looked for and found the previous year by Delgado, Roberts and Miller) and although he had considered the existence of central reward processes, Olds was working on the 'arousing' effects of electrical stimulation when he made his discovery. Noting a tendency for one rat to return to a point where he had previously been stimulated, Olds and Milner were quick

to exploit this phenomenon with an operant conditioning apparatus. Many researchers must previously have seen sniffing and approach behaviours following stimulation through implanted electrodes. The originality of the discovery lay in seeing the possible significance of this behaviour and examining it in a Skinner box.

In succeeding years Olds made major contributions to understanding self-stimulation behaviour. With Travis and Schwing, and later with M. E. Olds, he prepared what are still the most extensive maps of approach and avoidance areas in the rat brain. With Travis, Yuwiler and others he initiated investigations of the possible neurochemical basis of the phenomenon. His suggestion in 1960 that the major tranquillizers act specifically on the mechanisms of approach behaviour has recently attracted new interest in the light of the action of these drugs on dopaminergic mechanisms. Increasingly Olds became interested in single cell recordings as a method of investigation, but he never felt that these had given the answer he really wanted, the anatomical indentity of the reward mechanism itself.

Old's writings on self-stimulation included many provocative theories. He took an intense interest in new ideas and findings which might be relevant to the problem, and in recent years had been preoccupied with the possible role of monoamine neurones in reinforce-

ment. To the end of his life he remained at the centre of controversies concerning the functional significance of this behaviour and its neuroanatomical basis, and in retrospect it was perhaps fortunate that so much work in this field was gathered together at the Beerse conference in 1975 (*Brain Stimulation Reward*, edited by A. Wauquier and E. T. Rolls, Elsevier). James Olds must have impressed many of those present as the man best able to draw together the various strands of evidence in a coherent synthesis. Particular interest attaches therefore not only to his contributions to this symposium but also to the as yet unpublished monograph on Drives and Reinforcements completed a year before his death.

Olds modestly maintained that if he had not discovered electrical self-stimulation it would soon have been uncovered by someone else. This may be doubted, but even if true, few workers could have contributed his enthusiasm and imagination to developing a whole new field of psychophysiological work. He was a man who was willing to consider unusual concepts and paradoxical ideas but pursued them with great clarity. Everyone in the field will feel the loss of his critical intelligence and many will also acknowledge a debt of gratitude for his personal encouragement of their own efforts.

T. J. Crow

announcements

Appointments

Dr H. S. Bedson to the Chair of Medical Virology at the University of Birmingham.

Dr Leo A. Kaprio has been reappointed as Regional Director for Europe of the WHO.

Mr E. S. Booth, chairman of the Yorkshire Electricity Board, as the next President of the IEE.

Professor A. Lazenby, at present Vice-Chancellor of the University of New England, NSW, as the next Director of the Grassland Institute.

Professor D. R. Stranks, of the University of Melbourne, as Vice-Chancellor of the University of Adelaide.

Professor E. W. J. Mitchell, Head of the Department of Physics, as Deputy Vice Chancellor of the University of Reading.

Dr Derek Ogston, Reader in Medicine as Regius Professor of Physiology at the University of Aberdeen.

Dr Roger Grice, of Cambridge University, as Professor of Physical Chemistry at Manchester University.

Professor John Fraser Scott, of the University of Sussex, has been appointed Vice-Chancellor of La Trobe University, Melbourne.

Awards

The Faraday Division of the Chemical Society has awarded the 1976 Marlowe

Medal to **Dr James J. Burton** of the Exxon Research and Engineering Company for his theoretical work on microclusters.

The Finsen awards for 1976 have been made to **S. B. Hendricks** (Control of plant development by light), **H. F. Blum** (Skin and Cancer Hospital, Philadelphia, USA) (Photodynamic action and carcinogenesis by UV light), and **D. Shugar** (University of Warsaw, Poland) (Photochemistry and the structure of nucleic acids and proteins).

The SRC has awarded Senior Fellowships to **Dr A. Boksenberg,** of the Department of Physics, University College, London; **Professor A. Car-**

rington of the Department of Chemistry, University of Southampton; **Professor B. C. Clarke** of the Department of Genetics, University of Nottingham; **Dr P. H. Gaskell** of Pilkington Bros Ltd and the University of Cambridge; **Professor C. A. R. Hoare** of Queens University, Belfast; **Professor E. C. Zeeman** of the Department of Mathematics, Warwick University.

Meetings

October 11–15, **Clean Air**, Edinburgh (The Press and Information Officer, National Society for Clean Air, 136 North Street, Brighton BN1 1RG).

November 4–5, **Mutilation of Animals**, London (Symposium Organising Secretary, RSPCA Headquarters, Causeway, Horsham, Sussex RH12 1HG, UK).

November 8–10, **Manufacture of Superconducting Materials**, Port Chester, New York (Conference Coordinator, Technical Divisions and Activities, American Society for Metals, Metals Park, Ohio 44073).

November 17–18, **Agricultural Yield and Efficiency**, London (The Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, UK).

December 1–2, **Food Additives in the Balance**, Harrogate (Dr D. Howling, c/o Technical Division, CPC (United Kingdom) Ltd, Trafford Park Road, Trafford Park, Manchester M17 1PA, UK).

January 5–7, **Solid State Physics**, Manchester (Deadline for contributions: November 1) (Professor H. E. Hall, Department of Physics, University of Manchester, Manchester M13 9PL, UK).

January 18–19, **Optical Production Technology**, London (Mrs R. G. Keiller, SIRA Institute Ltd, South Hill, Chislehurst, Kent BR7 5EH, UK).

January 25, **Energy Transfer Mechanisms, Dosimetry, Dose-Response Relationships**, London (Professor J. H. Martin, Department of Medical Biophysics, Blackness Laboratory, University of Dundee, Dundee, UK).

February 16–18, **4th International Congress on Mutations: Biology and Society**, Paris (Congrès Service, 1, rue Jules Lefèbvre, F 75009, Paris, France)

March 17–18, **Perinatal Care**, New York (Dr Raymond L. Vande Wiele, Co-chairman of Symposium on Future Directions in Perinatal Care, College

of Physicians and Surgeons of Columbia University, Department of Obstetrics and Gynecology, 630 West 168th St, New York, N.Y. 10032).

March 29–31, **Neuromuscular Disorders**, Bath (Dr G. G. Lune, Department of Biochemistry, University of Bath, Bath BA2 7AY, UK).

April 17–30, **Chemically Induced Magnetic Polarisation**, Sogesta, Urbino, Italy (Professor L. T. Muus, Chemistry Institute, 140 Langelandsgade, DK-8000 Aarhus C, Denmark)

April 23–28, **Annual Meeting of the American Ceramic Society**, Chicago (Deadline for abstracts: November 20) Dr D. N. Winslow, School of Civil Engineering, Purdue University, West Lafayette, Indiana 47907).

April 25–29, **11th International Sym-**

posium on the **Remote Sensing of the Environment**, Ann Arbor, Michigan (Dr Jerald J. Cook, Environmental Research Institute of Michigan, PO Box 618, Ann Arbor, Michigan 48107).

May 1–7, **Stereochemistry**, Burgenstock, Switzerland (Professor P. Pino, Laboratorium fur Technische Chemie, ETH, Universitatsstr 16, CH-8092, Zurich, Switzerland).

May 23–27, **Safety at Sea**, London (The Conference Secretary, WEMT 1977, 10 Upper Belgrave Street, London SW1X 8BQ, UK).

August 29–September 1, **Drugs Affecting Lipid Metabolism**, Philadelphia (Deadline for abstracts: April 15) (Dr William L. Holmes, Scientific Secretary, Symposium on Drugs Affecting Lipid Metabolism, Lankenau Hospital, Philadelphia, Pennsylvania 19151).

August 30–September 2, **Biological Activity and Chemical Structure**, Noordwijkerhout, the Netherlands (Secretariat Department, c/o Merck Sharpe and Dohme B.V., Waarderweg 39, PO Box 581, Haarlem, the Netherlands).

August 31–September 2, **Astronomy and Astrophysics**, Christchurch, New Zealand (Astrophysics Conference Secretary, Department of Physics, University of Canterbury, Private Bag, Christchurch, New Zealand).

September 4–9, **13th International Symposium on Free Radicals**, Lyndhurst, Hampshire, UK (Professor A. Carrington, Chemistry Department, The University, Southampton SO9 5NH, UK).

September 11–16, **Pathology**, London (Professor A. Munro Neville, VIth European Congress of Pathology, Institute of Cancer Research, Fulham Road, London SW3 6JB, UK).

September 12–14, **Electron Microscopy and Analysis**, Glasgow (The Meetings Officer, Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

September 27–29, **Power Semiconductors and their Applications**, London (Deadline for abstracts: November 1) (Press Officer, IEE, Savoy Place, London WC2R 0BL, UK).

October 24–26, 1977, **Erosion: Prevention and Useful Applications**, Vail, Colorado (Deadline for abstracts: March 30) (Dr William F Adler, Effects Technology, Inc., 5383 Hollister Avenue, Santa Barbara, California 93111)

October 21, 1976

The price of trouble: £300

SHOULD university students be offered differing sizes of government grants depending on the subject they choose to take and its perceived relevance to national needs? The question has come into sharp focus in the United Kingdom with persistent rumours that the Department of Industry is trying to get engineering students paid an extra £300 on their annual grant. At present most students with state support get nominally identical grants, though some who receive grants from industry or the armed forces and who may have commitments after leaving university receive higher sums. Differential grants have been used in the past—in the 1930s potential teachers were given a supplement as undergraduates.

There are three questions which must be asked of any such scheme—is it needed; will it be effective; will it generate unnecessary trouble? There could be a need for differential grants if engineering graduates were in high demand, if universities had room for students and yet they were unforthcoming in sufficient quality and quantity. Obviously a simple label 'engineer' is inadequate for determining who is in high demand, and equally obviously many businesses which say they don't need more graduates are deceiving themselves. Even so, the supply of graduate engineers, whatever its defects, does not seem to have rung too many alarm bells. Nor, contrary to public opinion, are university engineering departments lonely places to be in these days. In 1976 there are 36% more students starting civil, mechanical and electrical engineering courses than there were in 1973 (during the same period the entry into mathematics, physics and chemistry dropped by 4%). The school academic attainments of engineering undergraduates are not conspicuously good, but it is by no means clear that £300 will buy quality; which brings us to the question of effectiveness of the measure.

If the measure turns out to be effective, it could easily be so by diverting students from adjacent disciplines: to collect £300 mathematicians would become mechanical engineers; physicists, electrical engineers; chemists, chemical engineers. Some effectiveness! Further, the measure can only be effective if schools are capable of responding to changing demands and are capable of giving wise advice to their pupils on whether

the money justifies the switch in individual cases—yet many believe it is in schools where counselling on engineering careers is inadequately done. And the sort of student who will be tempted by £300 is also likely to look at the way engineering salaries compare with those in other professions—and maybe to decide that how the Department of Industry and how industry itself rates him are two different things.

Finally, the troubles it will cause. If engineering, why not science, for technology uses research results. Why not economics, because it is an economic mess we are in. Why not business management, because our companies need to be run better. Why not agriculture, because food imports make a big hole in our balance of payments. Why not design, which sells commodities. Or art, music, drama, which bring in tourists. The idea once accepted in one instance could lead to an almost endless queue of special cases. And once the scheme is started, how is it stopped without undesirable effects? After all, when ICI cut its graduate recruitment of chemists one year the consequences reverberated for years in schools and universities. So when the government phases out its supplement there can be no doubt that it will depress engineering recruits.

So, for a variety of reasons, the £300 scheme seems to be all wrong. But that should not deflect us from a deep concern that engineering does need some sort of leg-up from its present low-prestige intellectually-unsatisfying status. One thing about which the Department of Indsutry should be talking seriously to the Department of Education and Science is whether schools can provide adequate support and encouragement to potential engineers. A second is whether too many universities don't impose rigid barriers between mathematics, science and engineering thereby preventing students from 'tasting' engineering without making an irrevocable commitment.

It is not clear that opposition to differential grants at undergraduate levels should necessarily mean opposition at the postgraduate level, where the sacrifice of an industrial salary for the spartan life of a higher degree may for many engineers be intolerable in a way that it is not for most other research students who lack outside attractions. □

A view from home

Andrew M. Sessler, Director of the Lawrence Berkeley Laboratory (LBL) at the University of California, Berkeley, responds here to the assessment of LBL carried by Nature *(August 12, page 528)*

THE article on LBL was, in my opinion, neither fair nor accurate. I acknowledge the right of a writer to put down what he believes he has observed, but I cannot in good conscience say that I recognise our Laboratory either in its past or present state. In describing its past, for example, the writer, Wil Lepkowski, quotes Robert Yaes on the failures of Lawrence's Laboratory to discover artificial radioactivity and nuclear fission. Those are true charges, but they should surely be considered against a background of the many revolutionary discoveries which were made in the 1930s when Lawrence's Laboratory led the world in nuclear science.

Many fundamental features of nuclear reactions, nuclear structure, radioactive decay, nuclear chemistry and artificial radioactivity were established. The Laboratory was the birthplace of the transuranium elements, and has active research currently in progress to search for possible superheavy elements. The Laboratory established the science of nuclear medicine before the Second World War, when most of the radioactive tracers employed in medicine today were discovered and the foundations were set for the tracer techniques and scintillation detector cameras that are now so commonly used in diagnostic medicine. LBL's eight Nobel Prizes in fact reflect its vitality in basic science throughout Lawrence's time.

Mr Lepkowski is correct in his point that LBL no longer dominates the world of high energy physics, but the sense of failure he attaches to this seems unwarranted. It would be absurd to expect that any laboratory could continue to dominate such a thriving field. Yet our high energy physicists from LBL are not in fact doing all that badly. When the *Nature* article appeared the high energy physics community throughout the world was excitedly discussing the first observation of a charmed particle by a long-standing Lawrence Berkeley Laboratory-Stanford Linear Accelerator collaborative group. This same collaboration had made a major discovery two years earlier of the ψ/J particle, at the same time that the same particle was discovered at Brookhaven, and subsequently they discovered the ψ'. Furthermore, the collaboration of LBL and SLAC is a joint project in every

sense of the word: they have been working together on this project for more than five years, using a national facility supported by the entire high energy physics community in the United States. LBL is proud to be an essential part of its design, construction and management, and can expect to continue to have a significant role in high energy physics research for decades to come.

Mr Lepkowski overlooks the strong and unique position that LBL occupies in heavy-ion nuclear physics. Our Laboratory has major programmes at its sector-focusing 88-inch cyclotron, the SuperHILAC and the Bevalac, the latter being the only source of relativistic heavy ions in the world. LBL accelerators are operated as national facilities and there are strong in-house experimental and theoretical groups. We are not blind to the fact that formidable competition is growing, particularly in Europe which is now allocating far more support to nuclear physics than is the United States, but at this time LBL is still considered by all to be a major international centre for nuclear physics.

Basic research is also very healthy at LBL in fields too numerous to catalogue in detail. Fundamental studies in biology and medicine work range from yeast genetics, physiology, and lipoprotein studies to radiobiology and nuclear medicine. LBL, in collaboration with others, is currently pioneering clinical trials on the efficiency of relativistic-energy heavy ions in cancer therapy. In molecular science we have some of the world's forefront studies on reactions in crossed molecular beams, on laser induced chemistry, and on quantum electrodynamic studies in high-Z hydrogen-like atoms.

In material science surface polaritons and plasmons are being studied by means of their nonlinear excitation through optical mixing of laser beams; and synchroton radiation is being employed, along with low energy electron diffraction (LEED), to ascertain the nature of catalytic surfaces. The fundamental understanding of alloys by use of electron microscopy and other advanced techniques has led to the ability to design steels and alloys of unprecedented toughness and hardness. From the field of astronomy there is the first measurment of the mass of

a neutron star. In sum, basic science at LBL is diverse, excellent and enthusiastically pursued.

Mr Lepkowski dwells negatively on changes going on in LBL to address changing national and societal needs and a new set of goals from its major funding agency, the US Energy Research and Development Administration. Adaptation to a changing world is a necessity for organisations as it is for individuals. Furthermore, it is simply false to state that the old leaders and, in particular, the Nobelists, are still the dominating leaders of the Laboratory. In fact the Director, the Deputy Director, and eight of the ten Associate Directors have held their positions for less than four years. We of the present management make no apologies for changing the character at LBL.

We can also point to numerous entries into new fields in which important contributions have already been made and which have exciting prospects for the future. Among these are geoscience, geothermal resource assessment, controlled thermonuclear power, metallurgy, catalysis, isotope separation, materials science, environmental and biological effects of energy technology pollutants, energy policy analysis, solar power, and energy conservation studies. In our experience, when we enter fields which are non-traditional for LBL the quality of our scientific staff is revealed by immediate innovative use of advanced experimental techniques and theoretical analysis which result in important or revolutionary contributions to the new fields.

I can give the example of photo-electron spectroscopy turned to the study of the role of power plant particulates in the catalytic conversion of SO_2 to (harmful) sulphates; or the development, by a scientist previously working on the Lamb Shift, of the most sensitive detector for heavy metals by Isotope Shifted Zeeman Atomic Absorption (IZAA); or the development of superconducting quantum interference devices (SQUID) to a sensitivity some orders of magnitude greater than that available elsewhere, and their direct application to geothermal resource exploration. Or I could cite our work, some years ago, which initiated concern over the catalytic destruction of the protective ozone layer by supersonic transports.

I could give several examples, but let it suffice to say that we feel comfortable in our new activities because we know we are doing excellent science and engineering on problems of importance to mankind. ☐

Exotic viruses

Arie Zuckerman offers this brief on some
of the diseases now attracting broad attention

A BRIEF perusal of the daily press over the past few months would reveal an incidence of unusual disease which, to many, seems quite remarkable. There have, most recently, been the illnesses reported from the Sudan, Nigeria, Zaire and Sierra Leone— now apparently identified, by the World Health Organisation last week, as Marburg disease. Work on the identification of Philadelphia's so-called Legion's Disease continues in the United States. Lassa fever meanwhile attracts considerable attention. Rabies and Swine influenza receive even greater emphasis. Even Bubonic Plague has been in the headlines.

Of the many viruses that can infect more than one species of animal, three are of particular current interest. Rabies, with a huge reservoir of infection in the wildlife population of most parts of the world, is now racing across Europe towards Britain, where it has not been endemic for more than half a century. Marburg disease, first identified nine years ago, is still not fully understood. And Lassa fever looms as an awesome viral infection in tropical Africa.

Marburg disease

Marburg virus (or "green monkey") disease, a severe, distinctive, febrile human illness, was first described in 1967. Thirty-one cases of illness with seven deaths in Germany and Yugoslavia were traced to direct contact with blood, organs or tissue cell cultures from a batch of African green monkeys caught in Uganda. Several secondary cases subsequently occurred in hospital personnel who had been in contact with blood from patients; one further case was apparently transmitted by sexual intercourse. Although 29% of the primary cases proved fatal, there were no deaths in the 6 secondary cases.

It soon became apparent that this was a previously unrecognised disease, caused by an infectious agent probably new to medical science. Laboratory work using guinea pigs and Rhesus and vervet monkeys revealed an elongated sinuous organism generally curled in the form of a figure 6 or a horseshoe with superficial resemblance to rabies virus. But Marburg virus is morphologically distinct and does not share any antigenic properties with rhabdoviruses or with any other known viruses.

The infection has been investigated

intensively since the first outbreak, but the natural cycle of transmission in nonhuman primates and perhaps other species of animals and the origin of the infection remain unknown. The disease has not hitherto been recognised in a sporadic form in Africa.

The first recognised outbreak of the disease in Africa, and the first since the original outbreak, occurred in South Africa in February, 1975. The victim, a young Australian man who had hitch-hiked through Rhodesia, died in a Johannesburg hospital; shortly afterwards his travelling companion and one of the nurses who had cared for him contracted the same disease. Both recovered. Virological investigations showed the outbreak was caused by the Marburg virus. As in the original outbreak in Marburg, when the virus was isolated from semen 83 days after the onset of illness evidence was obtained that the virus could persist in the body for at least 2–3 months after the initial attack; the virus in this case was isolated from the victim's eye fluid 80 days after the onset of the illness.

Lassa fever

The dramatic story of Lassa fever began when two missionary nurses from Lassa, in North-Eastern Nigeria, died in 1969 from a mysterious illness; a third, who was gravely ill and flown to the United States, recovered. Convalescent plasma from her was effective in the treatment of a laboratory worker, who acquired the infection while working with tissue cultures infected with blood from these patients.

The following year a further outbreak of Lassa fever killed 52% of 23 patients admitted to hospital in Nigeria. Dr Jeannette Troup, who was primarily responsible for drawing attention to this disease, also died of the infection. Since then further cases have occurred and 10 out of 21 medical workers have died from Lassa fever. Up to June, 1975 the disease was recognised on nine different occasions involving 114 officially recorded cases, two of which resulted from laboratory infections. Over a third of these infections were acquired by person-to-person spread within hospitals. Many other clinically suspect cases have since been uncovered from reviews of hospital records: retrospective searches through the medical literature have revealed references to cases closely resembling Lassa fever in the Central African Republic, Upper Volta, Nigeria and Sierra Leone. Since 1969, cases have occurred in Nigeria, Sierra Leone and Liberia, and serological evidence suggests the virus may have been active elsewhere in West and Central Africa. And of course recent cases identified in air travellers to Britain, the United States and Canada have received extensive press coverage.

The clinical spectrum of Lassa fever extends from very mild or inapparent illness to fulminating fatal infection. Among patients admitted to hospital the death rate is as high as 67%, with more fatalities among Caucasians than Asians. Intimate contact with any primary case appears to carry a high risk of infection; relatives or medical attendants providing direct personal or nursing care are particularly threatened. Cases have occurred among patients and hospital visitors who apparently had no direct contact with the primary cases. Only a few such tertiary infections have occurred, and the reasons for the interruption of
Lassa patient arrives in Hamburg from Nigeria

Keystone

outbreaks after the generation of secondary cases are not clear. It seems that, although the primary cases were highly infectious, the secondary cases were not.

Lassa virus is a member of the arenavirus genus, a group of enveloped RNA viruses with a virion of granules instead of a defined core. Along with Machupo virus (which causes Bolivian haemorrhagic fever) 'it 'produces a significant mortality in man. Lassa appears to have the greatest potential for direct spreading in human populations. It is related antigenically to the rodent-associated haemorrhagic viruses of South America and to lymphocytic choriomeningitis virus, a persistent infection of mice. It has been isolated from a single rodent species, the multimammate rat *Mastomys natalensis* in West Africa.

More recently, a virus closely related immunologically to Lassa virus was recovered from the tissues and organs of wild *Mastomys natalensis* captured in 1972 in Mozambique. This finding more than doubles the potential area of Lassa-like virus distribution in Africa The multimammate rat is the most widespread and commonest rodent in Africa south of the Sahara, and an ideal carrier to the domestic environment because of its semi-commensal habit and a combination of other factors, including an exceptionally high propagation rate. Whether all the *Mastomys* rodents are capable of maintaining and transmitting Lassa virus, is not known, and the ecological interrelationships between *Mastomys* and the presumed non-reservoir genera *Rattus* and *Mus* have yet to be determined. Carnivores, in particular dogs and cats which probably prey upon *Mastomys* and other rodents, have not yet been investigated as potential secondary hosts.

The Lassa virus may spill over from the rodent cycle to man by various routes including, for example, contamination with rodent urine, directly or on foodstuffs or through dust. The means by which the virus is spread from one person to another is not clear. Accidental inoculation with a sharp instrument or contact with blood has accounted for a few cases. The virus has been isolated from the pharynx and urine of patients, so that indirect airborne spread of the virus as well as mechanical transmission are most likely.

Lassa fever is not a disease which comes under international quarantine regulations, which at present offer the only effective means of reducing the risk of transmission. Transmission can be limited to some extent by surveillance, identification, and the hospitalisation and isolation of patients, but quarantine of households may have

to be considered by public health authorities, and ways of reducing rodent populations should be explored. The evacuation of patients presents special problems. Until effective methods of treatment and control become available and a suitable vaccine is developed, the epidemiological propensities of this infection may be very wide with the modern means of air travel.

Rabies

Rabies virus is a member of the rhabdovirus group, which includes a diverse collection of characteristic bullet-shaped RNA viruses from mammals, reptiles, fish, insects and plants. The concept of a single antigenic entity is no longer accepted since there are four recognised rabies-related viruses, although these appear to be confined to sub-Saharan Africa. Two of these viruses, Mokola and Duvenhage, are associated with fatal rabies-like human illness.

Rabies is a viral infection of the central nervous system which has been recorded in most domesticated and wild warm-blooded animals. The virus, present in salivary secretions, is transmitted mainly by bites or scratches, although the inhalation of minute droplets in the air can also lead to infection, and oral transmission has been demonstrated in experimental animals. The susceptibility of an animal depends on its age, the degree of infection, the site of introduction and the properties of the particular virus strain involved. Once the virus leaves the site of inoculation it usually passes to the central nervous system through the peripheral nerves. Once the · central nervous system has become infected the virus may multiply, attacking such tissues as the salivary and other glands, the kidneys, the brown fat, and, in some species, muscle and lung. In some infected organs the virus is found primarily within the nerves.

The effects of the disease on the nervous system and the change of behaviour in the victim are probably important to the mode of transmission. Typically, the sick animal (and this applies particularly to small carnivores) becomes unusually and indiscriminately aggresive, while in the earlier stages of infection timid animals become less restrained, approachable and friendly High population density and turnover and long incubation periods maintain the infection even though it is usually fatal Man is irrelevant to survival of the virus: there is no adequately documented case of human transmission of rabies, although a theoretical risk exists because the virus is present in secretions

The most important pool of infec-

tion in most areas of the world is the wildlife population, including, in particular, foxes. Examination of thousands of small wild rodents in the Americas has not revealed rabies infection, but in parts of Europe the isolation of rabies virus with unusually low virulence has been reported from wild rodents. The significance of this finding is not clear, and cannot be immediately associated with fox rabies. The ecology of bat rabies is intriguing· in the Americas, numerous species of bats have been found with rabies infections, but in many areas these infections are independent of other mammalian cycles. The disease is readily passed on to cattle by the bite of vampire bats during feeding; in Latin America, for example, bat rabies is estimated to have killed many hundreds of thousands of cattle. Over 170 human deaths from rabies have been attributed to vampire bats, which suck the blood of sleeping victims. But natural transmission from insectiverous bats to other terrestrial animals by biting has not been observed, and experimental transmission with infectious saliva has proved difficult.

The major problem caused by rabies, according to a paper from the Office of Health Economics in the UK, does not stem from its immediate effects, but from the medical, social and economic risks and the cost associated with its prevention Improved human diploid cell vaccines are in fact now becoming available for pre- and post-exposure prophylaxis in man, while supplies of human rabies immunoglobulin for passive immunisation and local wound treatment are expected to increase and developments in intensive care promise a better outlook for future victims.

The control of rabies in animals, on the other hand, presents considerable difficulties The international transfer of animals must be rigidly controlled. and strict precautions should be taken in the acquisition of mammals from the wild. The control of wildlife rabies is even more difficult Hormonal sterilisation can be effective experimentally but has not yet been used successfully in the field. The immunisation of wildlife may become feasible in the future, particularly oral immunisation of foxes using bait doped with live attenuated virus. The control of bat rabies requires further investigation. although inoculation of cattle with small amounts of anticoagulant has proved lethal for vampires. Similarly the backs of captured vampire bats can be smeared with anticoagulant mixed with petroleum jelly: their release has resulted in dramatic reduction in the number of bats, since the treated bats contaminated others in their colony by contact.   □

NUCLEAR TRADE

More words than action

International trade in nuclear technology was a key issue at the 20th annual meeting of the International Atomic Energy Agency (IAEA) held in Rio de Janeiro last month. Bruce Handler reports from Brazil

ONE reason the IAEA meeting was held in Latin America was to encourage a better understanding of the problems facing developing countries in the field of nuclear energy. Nearly 1,400 delegates who attended wound up hearing almost as much about problems IAEA members have with each other as they have with nuclear energy, because a good portion of the debate consisted of political tirades. But everyone was in favour of the further development of nuclear energy. The sharp divisions were over which countries should assume the responsibility for developing it, and to what extent.

Many industrialised nations expressed fears over putting sophisticated nuclear technology into the hands of underdeveloped Third World countries, principally because of the widely shared belief that such countries could be encouraged or provoked into diverting this knowhow for military purposes. A corollary fear was that terrorists could stage a raid on an underdeveloped country that possessed nuclear reactors and steal the necessary components for making an atom bomb, even if the country in which this occurred was actually using atomic energy only for peaceful purposes.

The Third World rebuttal of this position was that underdeveloped countries could never progress if they are not allowed to acquire modern technology, in nuclear energy as well as in other fields. Developing countries described as discrimination the desire on the part of industrialised nations to limit the spread of such technology.

The IAEA's director-general, Sigvard Eklund, noted that many Third World countries have not signed the 1970 Nuclear Non-Proliferation Treaty because of this feeling. He appealed to them to reconsider the political reasons which originally led to their taking such a position but later recognised, realistically, that when it comes to national pride, nations sometimes refuse to listen to the most soberly reasoned arguments.

The country most strongly opposed to the sharing of nuclear technology was the United States. The head of the US delegation, Robert C. Seamans Jr., director of the US Energy Research and Development Administration, said in an address that the USA did not want to see sophisticated atomic knowhow spread throughout the developing world.

He said that countries which are taught how to enrich their own uranium for use in nuclear reactors could use this knowhow to separate plutonium from uranium. This, in turn, Seamans stated, "can increase the risk of diversion (of fissionable material) to nuclear weapons and also the risk of terrorist activities." The United States was willing to enrich uranium for other countries and make it widely available, but it was a risk to international security to show developing nations how to do their own enriching. Seamans added that as a compromise, the IAEA could set up regional uranium-enriching centres, which would at least be under multinational control.

Yugoslavia presented a proposal for creating a multinational pool of nuclear resources, to make it easier for developing countries to begin or expand nuclear energy programmes.

The IAEA meeting, however, was basically a forum, rather than a policy-making session, and the best any single delegate could hope for was that others would consider the proposals discussed and take them back to their home governments for study and possible implementation.

The Third World view on technology sharing was expressed most emphatically by Hervasio de Carvalho, the president of Brazil's Nuclear Energy Commission. He labelled the preoccupation over safeguards and the spread of nuclear technology to underdeveloped nations as "exaggerated", and repeated what Brazilian government officials have been trying to

---

One complete session of the IAEA meeting was devoted to the scientific discussion of advances that have been made in the use of nuclear technology in food and agriculture. Among the highlights:

● Dr Maurice I. Fried, of the United States, director of the Joint FAO/IAEA Division of Atomic Energy in Food and Agriculture, gave a historical introduction to the use of nuclear techniques in the field of food and agriculture, and told delegates that isotope and radiation techniques "are neither esoteric nor so sophisticated that developing countries cannot apply them for the solution of practical problems." He noted that the bulk of the work of the joint FAO/IAEA programme he heads is aimed at helping developing countries use atomic energy to improve their agricultural output.

● Dr Dick De Zeeuw, of the Netherlands, general director of agricultural research of the Netherlands Ministry of Agriculture and Fisheries, offered the sombre forecast that by the year 2010 the world will have 1,800 million more people who consume less than the required daily amount of food than it does today, and that most of these new hunger victims will be in Southern and Southeast Asia. Many developing countries, he said, now lose from 20–40% of their crops after harvest; food-irradiation and related techniques could reduce this loss, but the main obstacle was the failure of policy-makers in developing countries to adopt the widespread use of atomic irradiation of food and to discard ineffective traditional methods.

● Dr K. Sundaram, of India, director of the biomedical group of the Bhabha Atomic Research Center in Bombay, made the point that effective food preservation techniques are difficult to transfer to underdeveloped ones, because of problems of money, materials, technology and energy of the poor nations' end. He said that developing nations around the world had failed to recognise irradiation's true importance, and criticised them for wrongly copying food preservation methods from developed countries, which, he noted, do not need to place so much importance on irradiation because of the already high standards of their food industries.

● Admar Cervellini, of Brazil, professor and head of the Physics and Meteorology Department of the University of Sao Paulo's Luiz de Queiroz Agricultural College, in Piracicaba, spoke about the work of Brazil's Centre for Nuclear Energy in Agriculture, of which he also is the head. The centre, which was set up with IAEA assistance, is now ten years old.

Dr Cervellini said that one of the centre's most practical achievements has been the development, through radiation mutation, of strains of beans with increased yield, with higher protein content, and with more resistance to Golden Mosaic disease. Seeds of the latter variety have been distributed to five other Latin American countries.

explain to the rest of the world since the controversial nuclear deal with West Germany in 1975: that Brazil, which is poor in oil, has low-grade coal and is quickly using up its feasibly exploitable hydroelectric potential, has no other alternative but atomic energy for meeting its future electric-power needs. And for reasons of national security and common sense, Brazil cannot remain dependent on outside suppliers for nuclear fuel—as the United States would like.

Carvalho pointed out that even though Brazil has not signed the Nuclear Nonproliferation Treaty (for the usual reason: opposition to the division of the world into an elite, industrialised "atomic club" and everyone else), it has submitted the agreement with West Germany to IAEA safeguard supervision. This, he said, is proof that Brazil is not going to make any bombs, adding that the world should accept the word of other countries that make similar pledges to use atomic energy only for peaceful purposes. (The IAEA Board of Governors, which met in Rio before the general meeting, approved safeguard provisions in two other major transfer-of-tech-

nology nuclear agreements: the one between Canada and Spain and that between France and South Africa.)

The Nigerian delegate's contention, that developing countries are in the IAEA "to be seen but not heard" and that they are "merely tolerated" by industrialised countries, did not seem to be reflected by the vote on a proposal sponsored by Iraq to admit the Palestine Liberation Organisation to the IAEA, as an observer. Of the 71 of the 110 member countries of the agency that were present for the vote, 46 voted in favour, 21 abstained and only four (Israel, the United States, South Africa and Costa Rica) voted no.

A move led by black African countries and supported by several socialist states to expel South Africa from the IAEA, on grounds that the Pretoria government does not represent the people, did not succeed. The best these countries could do was to get a motion passed to review South Africa's permanent seat on the Board of Governors, but with no action to be taken until the 1977 IAEA meeting. It is unlikely that even this watered-down proposal will bring results, because IAEA by-laws say the permanent

regional seats on the board must go to the countries in each specific area of the world that are the most advanced in nuclear technology. In Africa, there is no doubt that this is South Africa.

The effect of nuclear power stations on the environment was another topic to come up at the meeting. Eklund expressed veiled dislike for citizens' movements which have sprung up in countries such as the United States to stop further construction of nuclear reactors. The IAEA chief asserted that nuclear power plants are "friends of the environment." He said there has never been a fatal accident from nuclear causes at any of the 180 non-military nuclear installations now operating around the world. In contrast, Eklund noted, there have been serious accidents at hydroelectric plants, including the bursting of dams and the consequent widespread destruction of the environment.

Debate continued at the meeting on how best to dispose of waste material from nuclear reactors, by burying it in the ground, storing it in protected containers, dispersing it into the air or dumping it into the ocean. Perhaps predictably, no consensus was reached.

USA

New directions in lobbying

A new lobbying organisation concerned with global scientific environmental and social issues was established in the United States last week. Colin Norman reports from Washington

ALTHOUGH Washington is thick with lobbyists, public interest groups, research organisations and assorted political hucksters selling commodities ranging from the B-1 bomber to environmental awareness, the debut last week of a new 'citizens lobby' deserves —and is getting—more than passing attention.

Called 'New Directions', the organisation will be devoted to raising Washington's political consciousness (or at least, the consciousness of Washington's politicians) on such international issues as arms control, population growth, environmental pollution, and the depletion of resources. It will be an unabashed lobbying enterprise, focusing its attentions on the Congress. The reason it is already attracting considerable notice is that the list of its officers and governing board reads like a *Who's Who* of people concerned with such matters.

Full-time President of New Directions is Dr Russell W. Peterson, former

Governor of Delaware, who recently resigned as Chairman of the Council on Environmental Quality to head the new group. And the outfit's executive council will be chaired by Dr Margaret Mead, the well-known anthropologist who has long been active in public interest causes associated with science.

Planning for New Directions began in the Summer of 1974, when Norman Cousins, editor of *Saturday Review*, and Theodore M. Hesburgh, president of the University of Notre Dame, convened a small group to discuss whether such an organisation is needed and if so, what form it should take. During the past two years, the planning group has expanded to more than 100 people, including such luminaries as Robert McNamara, head of the World Bank, Kingman Brewster, President of Yale University, James Grant, president of the Overseas Development Council, Lester Brown, head of the Worldwatch Institute, and Sargent Shriver, former director of the Peace Corps.

The organisation will be similar in structure to Common Cause, a lobbying group which concentrates its attentions on domestic affairs. It will be a grass-roots organisation, financed by membership fees of $25 per year, solicitations for which will soon be made through a direct mail campaign

using membership lists of sympathetic organisations. New Directions hopes to attract at least 300,000 members, a number which would give it a very sizable war chest to put its message across.

Although the general nature of that message is evident from the concerns of the people associated with New Directions, priorities and details of the organisation's objectives are now being mapped out by groups of individuals working in the general areas of arms control, poverty and the widening economic gap between rich and poor nations, environment and natural resources, human rights, and governmental decision-making.

There are already numerous organisations active in Washington in those areas, but New Directions hopes to provide an additional function—political lobbying to get the concerns raised by various public interest organisations through to the policy makers. Few existing organisations have been able to take on such a role because they would lose considerable tax advantages if they were to indulge in direct lobbying activities. Essentially, they are registered as educational or research outfits. Though a recent change in the tax laws has lifted some of those restrictions, few organisations are geared up to lobby actively.

A statement put out last week by the planning committee of New Directions

describes its relationship with existing groups. "While the work of these groups provides an essential base of information and documentation," it says, "the missing element has been a force unlimited in scope and unfettered by tax prohibitions . . . No organisation has set out to mobilise existing resources to take hard political action on the critical measures which must be implemented to relieve the problems which now disrupt all economies, undermine political stability, suppress human freedoms, and directly threaten human survival throughout the world. Our purpose is to build such an organisation".

The idea is that New Directions will work closely with other groups—indeed, many of them have representatives on the organisation's governing board—and draw heavily on their research and expertise. It will select issues to lobby for, try to bring together informal coalitions of groups to work on them, and serve as a coordinating centre for exchange of relevant information. But its chief role will be to draw as much attention as possible to global problems and their potential solutions, through direct lobbying with members of Congress, government officials, corporate executives and so on. It will also take its case to the news media, organise local groups, go to court when necessary, and provide direct support to candidates for political offices.

Clearly, although the organisation will derive much of its influence from its star-studded cast of backers and officials, the crucial factor in its effectiveness will be the size of its membership. Politicians tend to listen more attentively to messages delivered by groups backed by large numbers of voters or by large amounts of cash which can be used for campaign support. If New Directions can succeed in attracting hundreds of thousands of members, its voice will be heard above the general background noise in Washington.

At this point, however, it is difficult to predict whether or not the organisation can count on that level of support. The people most likely to join are probably already members of existing groups such as Common Cause, and it remains to be seen whether the depth of their concerns extends to spending another $25. But there is at least one promising indication: the planning committee decided to go ahead only after a survey by a New York market research firm found considerable support for the goals of the organisation.

Another potential problem for the organisation is that unless it treads carefully, it may end up stepping on the toes of existing bodies which are already concerned with global problems

FDA's aerosol ban

In a statement which caught most observers here completely by surprise, the Food and Drug Administration (FDA) announced last week that it intends to phase out the use of chlorofluoromethanes (so-called fluorocarbons) as propellants in many types of aerosol sprays. Although the statement did not say when the ban would take effect, or how it would be implemented, FDA said that it would begin by requiring warning labels to be placed on aerosols containing fluorocarbons, and that the ban would be imposed in an "orderly" manner.

The agency's action is surprising since it follows hard on the heels of a major report by a committee of the National Academy of Sciences which recommended that regulation of fluorocarbons should be delayed for up to two years to allow time for more research on the mechanism by which fluorocarbons are believed to be breaking down the ozone layer. The academy report suggested that since the rate of destruction of the ozone layer is small, a two-year delay in regulation would present little additional hazard.

Dr Alexander M. Schmidt, the Commissioner of FDA, said last week, however, that additional research would narrow the range of uncertainty in the calculations of ozone depletion but it "won't change the ultimate regulatory situation". He argued that "given the effects on human health even a 2% ozone depletion from 'unessential' uses of fluorocarbons is undesirable".

"The known fact", Schmidt said, "is that fluorocarbon propellants primarily used to dispense cosmetics are breaking down the ozone layer. Without remedy, the result could be profound adverse impact on our weather and on the incidence of skin cancer in people. It's a simple case of

negligible benefit measured against possible catastrophic risk".

FDA's authority extends over foods, drugs and cosmetics. Thus, in theory, it has the power to regulate the formulation of products such as hair sprays and anti-perspirants which account for the bulk of aerosol uses of fluorocarbons. According to FDA's statement, the agency has authority over about 80% of all products now packaged in aerosol containers.

Schmidt said that FDA will publish details of its proposal to require labelling of aerosols containing fluorocarbons in mid-November, and that details of the phase-out programme will follow a few weeks later. The labelling programme itself should reduce consumption of fluorocarbon-containing products, and it will also help discourage stockpiling.

A spokesman for the DuPont company, the chief manufacturer of fluorocarbons, said last week that he was "astounded" by FDA's decision. The industry had regarded the academy's report as a victory because, in recommending a two-year delay in regulation, the academy had essentially backed the industry's argument that more research is needed to settle scientific uncertainties.

The industry is unlikely to take FDA's action lying down. Although industry spokesmen would not say last week how they expect to contest the ban, it is likely that they will ask for public hearings and, if necessary, go to court to prevent FDA putting its proposals into effect. One possible legal challenge may involve whether or not FDA has the authority under existing laws to take such action. The intensity of the industry's reaction will depend largely on how much time FDA gives it to phase out use of fluorocarbons, however, and that won't be known until towards the end of the year.

—such as the United Nations Association, the Overseas Development Council and the Worldwatch Institute. A check with people from some existing groups last week, however, found little fear that New Directions would steal their thunder or interfere with their goals. In fact, most welcomed the possibility of having a heavyweight group fighting for their causes.

Some supporters of New Directions also argued last week that one of the organisation's chief assets is the fact that it is headed by Russell Peterson. A PhD chemist who worked for DuPont for 26 years, Peterson is a

Republican who built a good reputation during his term as Governor of Delaware between 1969 and 1973. Peterson also knows his way around the Washington power structure very well, having served as chairman of the President's Council on Environmental Quality for three years. During that time, he took several independent stands, the latest of which was to call for immediate regulation of fluorocarbons in aerosol sprays. As one observer put it last week, a Republican, a former governor, and a former top adviser to the President are good credentials for a lobbyist. □

● The International Council of Scientific Unions (ICSU) is the latest organisation to seek a role for itself in the mounting debate over the risks and benefits associated with recombinant DNA experiments. At its 16th General Assembly, held in Washington last week, ICSU decided to establish a Committee on Genetic Experimentation to undertake a variety of tasks, ranging from the provision of advice and information to anyone who seeks it, to the support of lectures and training courses on safety techniques. The committee will also look into the possibility of providing ICSU support for a facility where large populations of cloned fragments of, for example, mouse or human DNA will be constructed and maintained for use by individual scientists. One aim of the committee is to use ICSU's considerable influence to try to ensure that the various controls on recombinant DNA experiments which are being imposed by countries around the world are consistent with each other. As Sir John Kendrew, ICSU's secretary general put it last week, it doesn't make much sense for one country to put very strict controls on the rsearch and for another to allow experiments to go ahead with few restrictions.

But Kendrew acknowledged that the countries with which ICSU deals "are sovereign states and you can't tell them what to do". The committee (which has the snappy acronym COGENE) will thus work behind the scenes, collecting and distributing information and providing assistance to national committees where it can.

Part of COGENE's task will be to ensure that recombinant DNA experiments are allowed to proceed, albeit under "appropriate and generally agreed safeguards". Dr William J. Whelan, who headed a committee which wrote COGENE's charter, noted last week, for example, that "the committee is not coming into being to preside over the demise of genetic manipulation and to that extent, ICSU is expressing a position".

The committee's most valuable function, however, may well be its provision of training courses and other technical assistance for recombinant DNA researchers. Kendrew pointed out that in smaller countries training in biological safety techniques may be limited, and ICSU could provide a needed service. The committee will also look into ways to aid in the distribution of strains of crippled hosts and vectors for recom-

binant DNA work, to help ensure that such strains are universally available.

As for the suggestion that COGENE should provide assistance for a central clone bank for fragments of mammalian DNA, the establishment of such a facility could greatly reduce the proliferation of some of the more hazardous cloning experiments. A similar clone bank is under con-

sideration in the United States, for use by American scientists.

● Once again, the Food and Drug Administration (FDA) has refused to allow the artificial sweetener cyclamate back on the market in the United States because of unanswered questions about its safety. Cyclamates were banned by FDA in 1969 on the basis of studies which indicated that they may cause bladder cancer in test animals when fed to them in large quantities; Abbott Laboratories, the manufacturer of the sweetener, contested the ruling and has been trying ever since to get it reversed. Last year, Abbott presented FDA with a petition, backed by a sheaf of test data, purporting to show that cyclamates are safe. But, last week, after turning Abbott's svidence over to an independent committee for its opinion, FDA rejected the petition, stating that "the data submitted . . . do not establish that cyclamate acid, calcium cyclamate, and sodium cyclamate are safe for their intended use". Undeterred, Abbott has demanded a public hearing, and will probably press its case in court if necessary. The final curtain has still not dropped on the longest-running food additive farce in Washington.

● The Presidential election campaign drones on, with scarcely any mention of scientific, environmental or related issues (the only exception being some discussion of ways to curb nuclear proliferation). But at least the candidates' thoughts on three matters of interest to the scientific community

have appeared in print.

The current issue of *Physics Today*, a magazine published by the American Physics Society, contains the responses of President Ford and Jimmy Carter to three questions put to them by the APS president, William Fowler. Fowler asked for their views on the role of science advisers in the White House, on national energy needs and the nuclear power programme, and on federal support for basic and applied science.

On the role of scientists in White House policy-making, Ford referred to the fact that Congress has recently approved legislation he introduced to re-establish a White House Office of Science and Technology Policy (OSTP). Noting that the director of the office will be the President's science adviser, Ford stated that he would "be one of my senior advisers and will also provide advice to other senior advisers". Carter offered no details of the role of his science adviser, though he argued that "the office of science adviser to the President should be ungraded immediately to provide a permanent and high-level relationship between the White House and the scientific community".

The two candidates differed most in their replies on energy policy. Ford contended that the use of both coal and nuclear power should be expanded, called the safety record of nuclear plants "outstanding", said he had increased federal spending on safety technology, and noted that his Administration was then in the middle of a review of its nuclear policy.

Carter said that no leadership now existed in the White House on energy planning. He said strong emphasis should be placed on energy conservation, arguing that "50% of our energy is wasted". On nuclear power, Carter stated that "we must make every effort to minimise our dependence on nuclear energy", though he emphasised that he does not support a nuclear moratorium. He said he would shift research priorities from nuclear power to conservation and non-nuclear options.

On federal research support, Ford said he had increased budgets for basic research and criticised Congress for reducing his budget proposals for the National Science Foundation. Carter noted that the federal government "has a crucial role to play in supporting development of new technologies which address national priorities".

● The aborted Soyuz 23 mission, although failing to accomplish any of its scientific objectives, has nevertheless won itself a place in the history of Soviet space flight by being the first major mission publicly acknowledged to have failed.

Hitherto, there has been a consistent policy for disguising failure, malfunction of lunar or interplanetary probes being disguised as part of the cover-all Kosmos programme (Kosmos 96 and 111, for example, were almost certainly originally intended as Venus and lunar probes respectively); a manned mission which returned to earth prematurely was explained in the media as having "successfully carried out its objectives". If, as in the case of the nightlanding of Soyuz 15, early return involved some special hazard, it was then claimed that the testing of recovery techniques under these difficult conditions was itself part of the programme. Even the tragic conclusion of the first Salyut–Soyuz mission, when the returning cosmonauts perished on re-entry, was offset by official pronouncements that all experiments had been successfully concluded and that scientifically speaking the mission had been entirely successful.

This reticence regarding setbacks was not lifted to any great extent in the preparatory work for the joint Apollo–Soyuz flight, for which the Soviet planners supplied information on a "need-to-know" basis, and there was relatively little discussion of past missions. Exchange of scientific information is a major concept of detente; the effective acknowledgement of difficulties both in the mission of Soyuz 23 to the Salyut 5 spacelab and in its return and landing may prove to be a sign of greater openness on the part of the Soviet space planners.

● The Far Eastern Science Centre of the Soviet Academy of Sciences is failing to make a proper practical contribution to the national economy. That, at least, is the finding of a special enquiry by the People's Monitoring Committee of the USSR. Over the past five years the Institutes of the Centre have carried out research on "more than 400 topics of a theoretical and practical character", notably in geology, vulcanology and marine resources. But, says the report, there were serious "derelictions" in the institutes' work which have prevented the proper utilisation of scientific potential and resources.

Too little is being done to apply the results of completed research to the national economy; during the last Five Year Plan, only 20 projects "with a confirmed economic effect" were realised, and out of 142 proposed inventions, only 42 received patents. The majority of research resulted merely in publications and "unplanned-for" monographs. The Centre is therefore deemed to be failing to carry out one of its fundamental functions, that of coordinat-

ing research "within the framework of the regions".

The development of the local resources and potentialities of Siberia and the Soviet Far East was the main reason for the founding of local Filials of the All-Union Academy, and the combining of existing Institutes into "Science Centres". Thus the Buryat Filial of the Siberian Branch of the Academy of Sciences of the USSR, which has recently celebrated its tenth anniversary, concentrates on solid state physics, rare-metal chemistry, and polymer synthesis—all in the name of local development—as well as the "propagation of electromagnetic waves in the conditions of the Trans-Baikal area", which, it is claimed, has brought television to more than 80% of the inhabitants of Buryatia.
